Status of Pacific ocean perch (*Sebastes alutus*) along the US west coast in 2017

Contents

Executive Summary

Stock

This assessment reports the status of the Pacific ocean perch rockfish (*Sebastes alutus*) off the US West Coast from Northern California to the Canadian Border using data through 2017. Pacific ocean perch are most abundant in the Gulf of Alaska and have observed off of Japan, in the Bering Sea, and south to Baja California, although they are sparse south of Oregon and rare in southern California. Although catches north of the US-Canada border were not included in this assessment, it is not certain the connectivity of these populations with contribution to the biomass possibly through adult migration and/or larval dispersion. To date, no significant genetic differences have been found in the range covered by this assessment.

Landings

The first year that harvest of Pacific ocean perch exceeded 1 mt off the US West Coast first occurred in 1918. Catches ramped up in the 1940s with large removals in Washington waters. During the 1950s the removals primary occurred in Oregon waters with catches from Washington declining following the 1940s. The largest removals occurring between 1966-1968 were largely a result of harvest by foreign vessels. The fishery proceeded with more moderate removals ranging between 1165 to 2619 metric tons (mt) per year between 1969 and 1980. Removals generally declined from 1981 to 1994 to between 1031 and 1616 mt per year. Pacific ocean perch was declared overfished in 1999, resulting in large reductions in harvest in recent years since the declaration. Since 2000, catches of Pacific ocean perch have ranged between 54-267 mt, with catches in 2016 totaling 65 mt.

Pacific ocean perch are a desirable market species and discarding has historically been low. However, management restrictions (e.g. trip limits) have resulted in increased discarding since the early 1990s. During the 2000s discarding increased for Pacific ocean perch due to harvest restrictions imposed to allow rebuilding, with estimated discard rates from the bottom trawl fishery peaking in 2009 and 2010 to discard rates of 50.4%, prior to implementation of catch shares in 2011. Since 2011, discarding of Pacific ocean perch has been estimated to be less than 3.5% based on observer data.

Table a: Landings (mt) for the past 10 years for Pacific ocean perch by fleet.

Year	California	Oregon	Washington	At-sea Hake	Survey	Total Landings
2007	0.15	83.65	45.12	4.05	0.58	133.55
2008	0.39	58.64	16.61	15.93	0.80	92.36
2009	0.92	58.74	33.22	1.56	2.72	97.17
2010	0.14	58.00	22.29	16.87	1.68	98.98
2011	0.12	30.26	19.66	9.17	1.94	61.14
2012	0.18	30.41	21.79	4.52	1.62	58.51
2013	0.08	34.86	14.83	5.41	1.71	56.89
2014	0.18	33.91	15.82	3.92	0.57	54.40

Data and Assessment

This a new full assessment for Pacific ocean perch which was last assessed in 2011. In this assessment, all aspects of the model including catches, data, and modelling assumptions were re-evaluated as much as possible. The assessment was conducted using the length- and age-structured modeling software Stock Synthesis (version 3.30.03.05). The coastwide population was modeled assuming separate growth and mortality parameters for each sex (a two-sex model) from 1918 to 2017, and forecasted beyond 2017.

All of the sources of data for Pacific ocean perch have been re-evaluated for 2017, excluding the historical fishery catch-per-unit time series. Changes of varying degrees have occurred in the data from those used in previous assessments. These current data represent the best available scientific information. The landings history has been updated and extended back to 1918. Harvest was negligible prior to that year. Survey data from the Alaska and Northwest Fisheries Science Centers have been used to construct indices of abundance using analyzed using a spatio-temporal delta-model. Length, marginal age or conditional age-at-length compositions were also created for each fishery independent data source.

The definition of fishing fleets have been changed from those in the 2011 assessment. Three fishing fleets were specified within the model: 1) a combined bottom trawl, mid-water trawl and fixed gear fleet where only a small fraction of Pacific ocean perch occurring by fixed gear (termed the fishery fleet), 2) the historical foreign fleet, and 3) the At-sea hake fishery. The fleet grouping were based on discarding practices. The fishery fleet estimated a retention curve based upon discarding data and known management restrictions. However, very little if any discarding is assumed to have occurred by the foreign fleet and the catch reported by the At-sea hake fishery accounts for both discarded and landed fish and hence, no additional mortality was estimated for each of these fleets.

The assessment uses landings data and discard-fraction estimates; catch-per-unit-of-effort and survey indices; length or age composition data for each year and fishery or survey (with conditional age-at-length compositional data for the NWFSC shelf-slope survey); information on weight-at-length, maturity-at-length, and fecundity-at-length; priors on natural mortality and the steepness of the Beverton-Holt stock-recruitment relationship; and estimates of ageing error. Recruitment at "equilibrium biomass", length-based selectivity of the fishery and surveys, retention of the fishery, catchability of the surveys, growth, the time-series of biomass, age and size structure, and current and projected future stock status are outputs of the model. Natural mortality and steepness were fixed in the final model. This was done due to relatively flat likelihood surfaces, such that fixing parameters and then varying them was deemed the best way to characterize uncertainty.

Although there are many types of data available for Pacific ocean perch since the 1980s, which were used in this assessment, there is little information about steepness and natural mortality. Estimates of steepness are uncertain partly because of variable recruitment. Uncertainty in natural mortality is common in many fish stock assessments even when length and age data are available.

A number of sources of uncertainty are explicitly included in this assessment. This assessment includes gender differences in growth, a non-linear relationship between individual spawner biomass and effective spawning output, and an updated relationship between length and maturity, based upon non-published information (M. Head, personal communication, NOAA, NWFSC). As is always the case, overall uncertainty is greater than that predicted by a single model specification. Among other sources of uncertainty that are not included in the current model are the degree of connectivity between the stocks of Pacific ocean perch off of Vancouver Island, British Columbia and those in PFMC waters, and the effect of climatic variables on recruitment, growth and survival of Pacific ocean perch.

A reference case was selected which adequately captures the central tendency for those sources of uncertainty considered in the model.

Stock Biomass

The predicted spawning biomass from the base model generally showed a slight decline over the time series until 1966 when the foreign fleet began. A short, but sharp decline occurred, followed by a period of the stock biomass stabilizing or with a minimal decline until the late 1990s. The stock showed increases in stock size following the year 2000 due to a combination of strong recruitment and low catches. The 2017 estimated spawning biomass relative to unfished equilibrium spawning biomass is above the target of 40% of unfished spawning biomass is 76.1% (˜95% asymptotic interval: ± 53.8%-98.4%). Approximate confidence intervals based on the asymptotic variance estimates show that the uncertainty in the estimated spawning biomass is high.

Table b: Recent trend in estimated spawning output (million eggs) and relative spawning output.

Year	Spawning Output (million eggs)	˜ 95% confidence interval	Estimated depletion	˜ 95% confidence interval
2008	3211.00	1362 - 5060	0.48	0.330 - 0.638
2009	3346.00	1425 - 5267	0.50	0.345 - 0.664
2010	3438.00	1467 - 5408	0.52	0.355 - 0.681
2011	3500.00	1496 - 5504	0.53	0.362 - 0.693
2012	3545.00	1521 - 5570	0.53	0.368 - 0.701
2013	3584.00	1544 - 5625	0.54	0.373 - 0.708
2014	3727.00	1618 - 5835	0.56	0.390 - 0.733
2015	4118.00	1812 - 6425	0.62	0.435 - 0.807
2016	4620.00	2054 - 7186	0.70	0.491 - 0.902
2017	5047.00	2259 - 7835	0.76	0.538 - 0.984

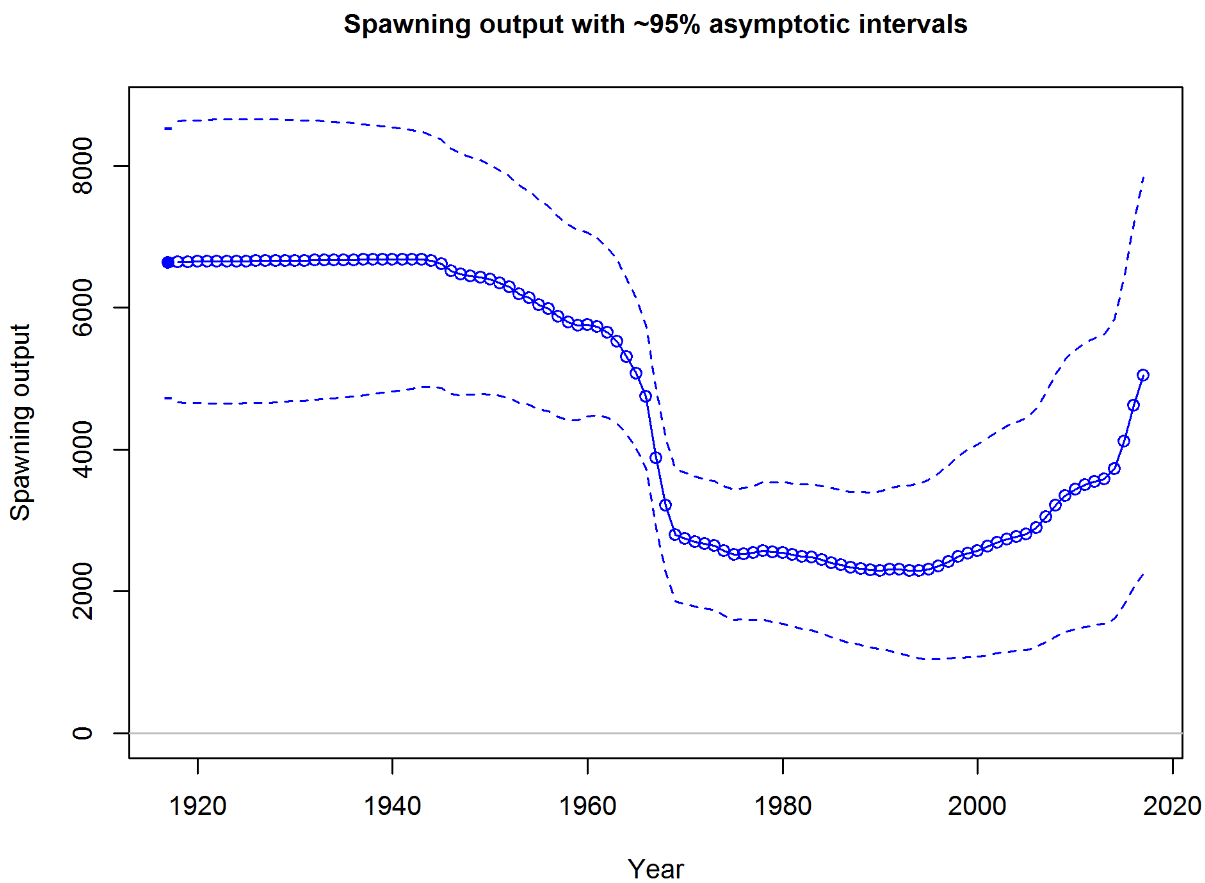

Figure b: Time-series of spawning output trajectory (circles and line: median; light broken lines: 95% credibility intervals) for the base case assessment model.

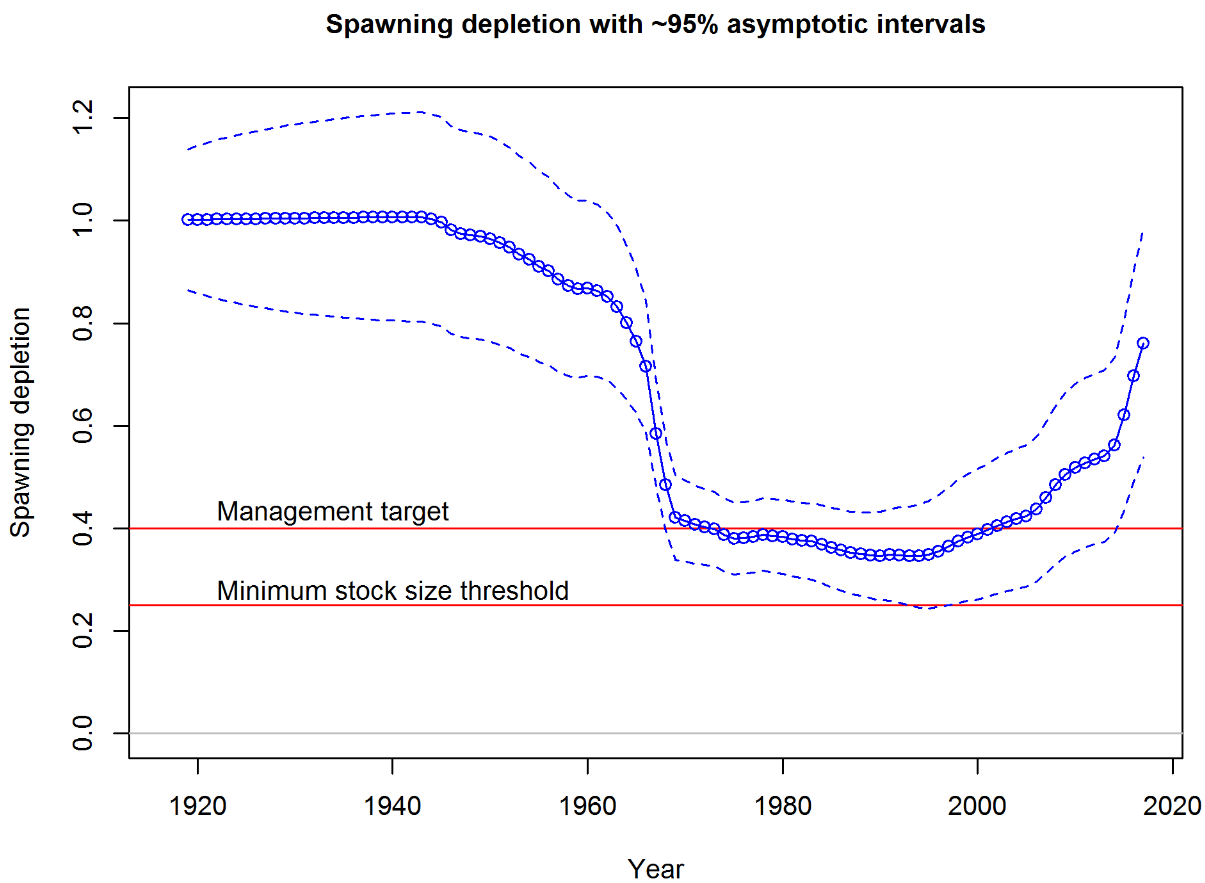

Figure c: Estimated relative spawning biomass (depletion) with approximate 95% asymptotic confidnce intervals (dashed lines) for the base case assessment model.

Recruitment

Recruitment deviations were estimated for the entire time-series modeled. There is little information regarding recruitment prior to 1965, and the uncertainty in these estimates is expressed in the model. Historically, there are estimates of large recruitments in 1999 and 2000. In recent years, a recruitment of unprecedented size is estimated to have occurred in 2008 but is highly uncertain. Additionally, there is early evidence of a strong recruitment in 2013. The four lowest recruitments estimated within the model (in ascending order) occurred in 2012, 2003, 1998, and 2005.

Table c: Recent estimated trend in recruitment and estimated recruitment deviations determined from the base model

Year	Estimated Recruitment	˜ 95% confidence interval	Estimated Recruitment Devs.	˜ 95% confidence interval

Figure d: Time-series of estimated Pacific ocean perch recruitments for the base-case model with 95% confidence or credibility intervals.

Exploitation status

The spawning biomass of Pacific ocean perch reached a low in 1994. Catches for Pacific ocean perch decreased significantly in 2000 compared to previous years. The estimated relative biomass was possibly below the overfished level in the early 2000s, but has likely remained above that level otherwise, and currently is significantly greater than the 40% unfished spawning biomass target. Throughout the late 1960s and 1970s the exploitation rate and (1-SPR)/(1-$SPR_{50\%}$) were mostly above target levels. Recent exploitation rates on Pacific ocean perch were predicted to be significantly below target levels.

Table d: Recent trend in spawning potential ratio (1-SPR)(1-$SPR_{50\%}$) and summary exploitation rate for Pacific ocean perch.

Year	(1-SPR)/(1-SPR50%)	˜ 95% confidence interval	Exploitation rate	˜ 95% confidence interval
2007	0.104	0.046 - 0.162	0.002	0.001 - 0.003

2016	0.028	0.012 - 0.043	0.001	0.000 - 0.001

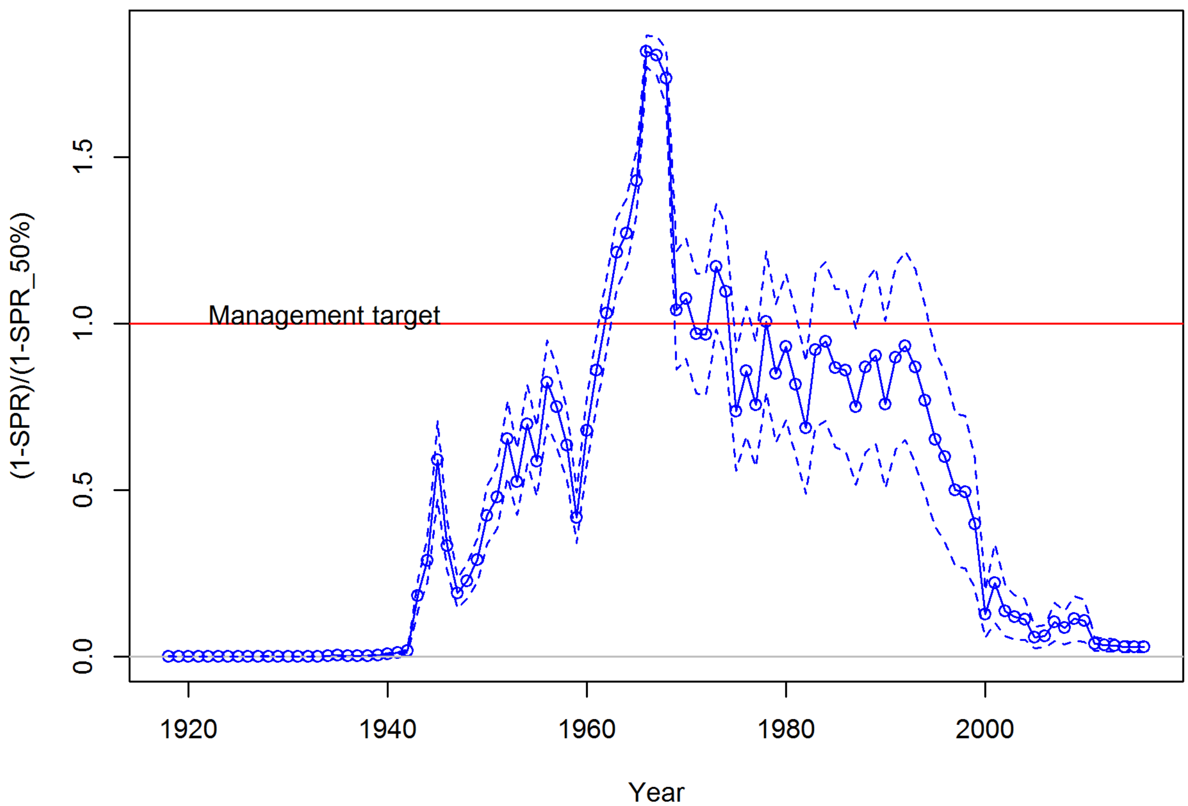

Figure e: Estimated spawning potential ratio (1-SPR)/(1-SPR50%) for the base-case model. One minus SPR is plotted so that higher exploitation rates occur on the upper portion of the y-axis. The management target is plotted as a red horizontal line and values above this reflect harvests in excess of the overfishing proxy based on the SPR50% harvest rate. The last year in the time series is 2016.

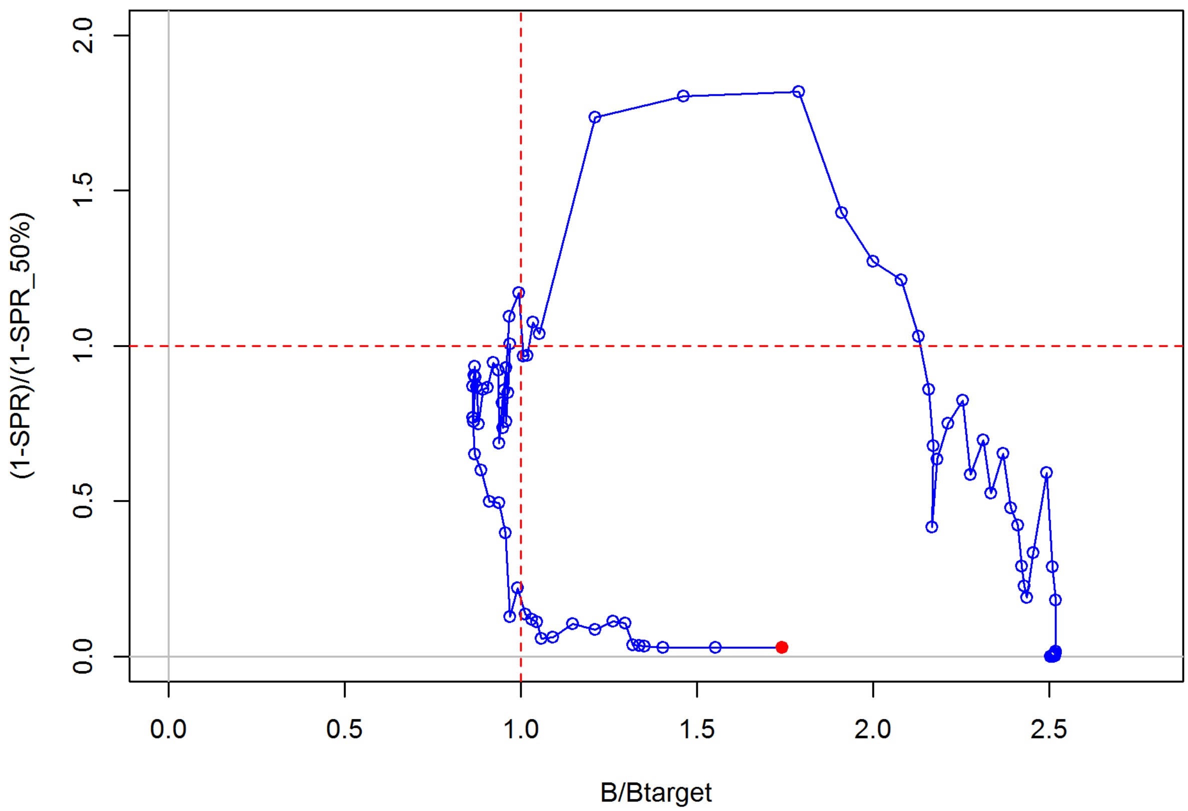

Figure f: Phase plot of estimated relative (1-SPR)/(1-SPR50%) vs. relative spawning biomass for the base case model. Relative biomass is the annual spawning biomass divided by the unfished spawning biomass.

Ecosystem Considerations

Rockfish are an important component of the California Current ecosystem along the US west coast, with its more than sixty five species filling various niches in both soft and hard bottom habitats from the nearshore to the continental slope, as well as near bottom and pelagic zones. Pacific ocean perch are generally considered to be semi-demersal but, there can at times, be a significant pelagic component to their distribution.

Recruitment is one mechanism by which the ecosystem may directly impact the population dynamics of Pacific ocean perch. The 1999 cohort for many species of rockfish was large - sometimes significantly so. Long-term averages suggesting that environmental conditions may influence the spawning success and survival of larvae and juvenile rockfish. Pacific ocean perch showed an above average recruitment deviation in 1999 and 2000. The specific pathways through which environmental conditions exert influence on Pacific ocean perch dynamics are unclear; however, changes in water temperature and currents, distribution of prey and predators, and the amount and timing of upwelling are all possible linkages. Changes in the environment may also result in changes in length-at-maturity, fecundity, growth, and survival which can affect the status of the stock and its susceptibility to fishing. Unfortunately, there are few data available for Pacific ocean perch that provide insights into these effects.

Fishing has effects on both the age structure of a population, as well as the habitat with which the target species is associated. Fishing often targets larger, older fish, and years of fishing mortality results in a truncated age-structure when compared to unfished conditions. Rockfish are often associated with habitats containing living structure such as sponges and corals, and fishing may alter that habitat to a less desirable state. This assessment provides a look at the effects of fishing on age structure, and recent studies on essential fish habitat are beginning to characterize important locations for rockfish throughout their life history; however there is little current information available to evaluate the specific effects of fishing on the ecosystem issues specific to Pacific ocean perch.

Reference Points

This stock assessment estimates that Pacific ocean perch are above the biomass target. Due to the large 2008 year-class, an increasing trend in spawning biomass was estimated in the base model. The estimated relative biomass level in 2017 is 76.1% (˜95% asymptotic interval: $\pm$ 53.8%-98.4%), corresponding to an unfished spawning output of 5047 million eggs (˜95% asymptotic interval: 2259-7835 million eggs). Unfished age 3+ biomass was estimated to be 139810 mt in the base case model. The target spawning output based on the biomass target ($SB_{40\%}$) is 2653.2 million eggs, which gives a catch of 1748.2 mt. Equilibrium yield at the proxy F_{MSY} harvest rate corresponding to $SPR_{50\%}$ is 1764.8 mt.

Table e: Summary of reference points and management quantities for the base case.

Quantity	**Estimate**	**~95% Confidence Interval**
Unfished spawning output (million eggs)	6633.1	4736.7 - 8529.5
Unfished age 3+ biomass (mt)	139810	100052.5 - 179567.5
Unfished recruitment (R0, thousands)	11665.7	8801.4 - 15462.1
Spawning output(2017 million eggs)	5047.2	2259.2 - 7835.1
Depletion (2017)	0.761	0.538 - 0.984
Reference points based on $\mathbf{SB_{40\%}}$		
Proxy spawning output ($B_{40\%}$)	2653.2	1894.7 - 3411.8
SPR resulting in $B_{40\%}$ ($SPR_{B40\%}$)	0.55	0.55 - 0.55
Exploitation rate resulting in $B_{40\%}$	0.028	0.028 - 0.029
Yield with $SPR_{B40\%}$ at $B_{40\%}$ (mt)	1748.2	1252.4 - 2244
Reference points based on SPR proxy for MSY		
Spawning output	2211	1578.9 - 2843.2
SPR_{proxy}	0.5	
Exploitation rate corresponding to SPR_{proxy}	0.034	0.033 - 0.034
Yield with SPR_{proxy} at SB_{SPR} (mt)	1764.8	1264.8 - 2264.8
Reference points based on estimated MSY values		
Spawning output at MSY (SB_{MSY})	2315.7	1649.6 - 2981.8
SPR_{MSY}	0.512	0.51 - 0.514
Exploitation rate at MSY	0.032	0.032 - 0.033
MSY (mt)	1766.7	1266.1 - 2267.4

Management Performance

Exploitation rates on Pacific ocean perch exceeded MSY proxy target harvest rates during the 1960s and 1970s, resulting in sharp declines in the spawning output. Exploitation rates subsequently declined to rates at or below the management target in the 1980s. Management restrictions imposed in the 1990s further reduced exploitation rates. An overfished declaration for Pacific ocean perch resulted in very low exploitation rates since 2001 with the ACLs being set far below the OFL and ABC values.

Table f: Recent trend in total catch and commercial landings (mt) relative to the management guidelines. Estimated total catch reflect the commercial landings plus the model estimated discarded biomass.

Year	OFL (mt; ABC prior to 2011)	ABC (mt)	ACL (mt; OY prior to 2011)	Total landings (mt)	Estimated total catch (mt)

Research and Data Needs

There are many areas of research that could be improved to benefit the understanding and assessment of Pacific ocean perch. Below, are issues that are considered of the importance.

1. **Natural mortality**: Uncertainty in natural mortality translates into uncertain estimates of status and sustainable fishing levels for Pacific ocean perch. The collection of additional age data, re-reading of older age samples, reading old age samples that are unread, and improved understanding of the life-history of Pacific ocean perch may reduce that uncertainty.

2. **Steepness**: The amount of stock resilience, steepness, dictates the rate at which a stock can rebuild from low stock sizes. Improved understating regarding the steepness of US west coast Pacific ocean perch will reduce our uncertainty regarding current stock status.

3. **Basin-wide understanding of stock structure, biology, connectivity, and distribution:** This is a stock assessment for Pacific ocean perch off of the west coast of the US and does not consider data from British Columbia or Alaska. Further investigating and comparing the data and predictions from British Columbia and Alaska to determine if there are similarities with the US west coast observations would help to define the connectivity between Pacific ocean perch north and south of the US-Canada border.

1 Introduction

1.1 Basic Information

Pacific ocean perch (*Sebastes alutus*) are most abundant in the Gulf of Alaska, and have been observed off of Japan, in the Bering Sea, and south to Baja California, although they are sparse south of Oregon and rare in southern California. While genetic studies have found three populations of Pacific ocean perch off of British Columbia related to unique geography and oceanic conditions (Seeb and Gunderson 1988, Withler et al. 2001) with, notably, a separate stock off of Vancouver Island, no significant genetic differences have been found in the range covered by this assessment. Pacific ocean perch show dimorphic growth, with females reaching a slightly large size than males. Males and females are equally abundant on rearing grounds at age 1.5.

The Pacific ocean perch population has been modeled as a single stock off of the US west coast (essentially northern California to the Canadian border, since Pacific ocean perch are seen extremely rarely in central and southern California). Good recruitments show up in size-composition data throughout all portions of this area, which supports the single stock hypothesis. This assessment includes landings and catch data for Pacific ocean perch from the states of Washington, Oregon and California, along with records from foreign fisheries, the At-sea hake fleet, and fishery-independent surveys.

Prior to 1966, the Pacific ocean perch resource off of the northern portion of the US west coast was harvested almost entirely by Canadian and United States vessels. Harvest was negligible prior to 1940, reached 1367 mt in 1950, 3243 mt in 1961 and 7635 mt in 1965. Catches increased dramatically after 1965, with the introduction of large distant-water fishing fleets from the Soviet Union and Japan. Both nations employed large factory stern trawlers as their primary method for harvesting Pacific ocean perch. Peak removals are estimated at 18883 mt in 1966 and 14591 mt in 1967. These numbers are based upon a re-analysis of the foreign catch data (Rogers 2003), which focused on deriving a more realistic species composition for catches previously identified only as Pacific ocean perch. Catches declined rapidly following these peak years, and Pacific ocean perch stocks were considered to be severely depleted throughout the Oregon-Vancouver Island region by 1969 (Gunderson 1977, Gunderson et al. 1977). Landed harvest averaged 1377 mt over the period 1977-94. Landings have continued to decline since 1994, primarily due to more restrictive management (Table 1 and Figure 1).

Prior to 1977, Pacific ocean perch in the northeast Pacific were managed by the Canadian Government in its waters and by the individual states in waters off of the United States. With implementation of the Magnuson Fishery Conservation and Management Act (MFCMA) in 1977, US territorial waters were extended to 200 miles from shore, and primary responsibility for management of the groundfish stocks off Washington, Oregon and California shifted from the states to the Pacific Fishery Management Council (PFMC) and the National Marine

Fisheries Service (NMFS). At that time, however, a Fishery Management Plan (FMP) for the West Coast groundfish stocks had not yet been approved. In the interim, the state agencies worked with the PFMC to address conservation issues. In 1981, the PFMC adopted a management strategy to rebuild the depleted Pacific ocean perch stocks to levels that would produce Maximum Sustainable Yield (MSY) within 20 years. On the basis of cohort analysis (Gunderson 1978), the PFMC set Acceptable Biological Catch (ABC) levels at 600 mt for the US portion of the Vancouver INPFC area and 950 mt for the Columbia INPFC area. To implement this strategy, the states of Oregon and Washington each established landing limits for Pacific ocean perch. Trawl trip limits of various forms remained in effect through 2016 (Table 2).

Age estimates for Pacific ocean perch prior to the 1980s were made via surface ageing of otoliths, which misses the very tight annuli at the edge of the otolith once the fish reaches near maximum size. Ages are highly biased by around age 10-12, and maximum age was estimated to be in the 20s, which lead to an overestimate of the natural mortality rate and the productivity of the stock. Using break and burn methods, Pacific ocean perch have been aged to over 100 years. Research surveys have been used to provide fishery-independent information about the abundance, distribution, and biological characteristics of Pacific ocean perch. A coast-wide survey of the rockfish resource was conducted in 1977 (Gunderson and Sample 1980) and was repeated every three years through 2004 (referred to as the 'Triennial survey'). The National Marine Fisheries Service (NMFS) coordinated a cooperative research survey of the Pacific ocean perch stocks off Washington and Oregon with the Washington Department of Fisheries (WDFW) and the Oregon Department of Fish and Wildlife (ODFW) in March-May 1979 (Wilkins and Golden 1983). This survey was repeated in 1985 (referred to as the Pacific ocean perch survey). Two slope surveys have been conducted off the West Coast in recent years, one using the research vessel Miller Freeman, which ended in 2001 (referred to as the 'AFSC slope survey'), and another ongoing cooperative survey using commercial fishing vessels which began in 1998 as a DTS (Dover sole, thornyhead and sablefish) survey and was expanded to other groundfish in 1999 (referred to as the 'NWFSC slope survey'). In 2003, this survey was expanded spatially to include the shelf. This last survey, conducted by the NWFSC, continues to cover depths from 30-700 fathoms (55-1280 meters) on an annual basis (referred to as the 'NWFSC shelf-slope survey').

1.2 Summary of Management History

The landings of Pacific ocean perch have been historically governed by harvest guidelines and trip limits, while recently management has imposed total catch harvest limits in the form of overfishing limits (OFLs), acceptable biological catches (ABCs), and annual catch limits (ACLs). A trawl rationalization program, consisting of an individual fishing quota (IFQ) catch shares system was implemented in 2011 for the limited entry trawl fleet targeting non-whiting groundfish, including Pacific ocean perch, and the trawl fleet targeting and delivering whiting to shore-based processors. The limited entry at-sea trawl sectors (motherships and catch-processors) that target whiting and process at-sea are managed in a system of harvest cooperatives.

Limits on Pacific ocean perch were first established in 1983 (Table 2). These were implemented as area closures, trip limits, and cumulative landing limits. In 1999, Pacific ocean perch was declared overfished with the assessment estimating the spawning output below the management limit (25% of virgin biomass). In reaction to the overfished deceleration, harvest limits were reduced relative to previous years and a rebuilding plan was implemented in 2001 with recent ACLs being set well below the estimated OFLs(Table 3).

1.3 Fisheries off Canada and Alaska

Pacific ocean perch can be found in waters off the US west coast and northward through Alaskan waters. In contrast the Pacific ocean perch stock off the US west coast, each assessed portion of the stock in Canada and Alaskan waters have historically been estimated to be above management targets. The subset of the stock off the US west coast represents the tail of the species distribution with little to no Pacific ocean perch being encountered south of northern California. The most recent updated assessments for the Bering Sea and the Gulf of Alaska stocks determined that neither stock are in an overfished state and recommended and acceptable biological catch of 43,723 mt and 23,918 mt, respectively, for 2017.

In Canadian waters Pacific ocean perch has the largest single-species quota, accounting for approximately 25% of all rockfish landings by weight in the bottom trawl fleet. The Canadian Pacific ocean perch stock is broken into three separate areas that are individually assessed. The status of the stock within each area are above Canadian management targets.

2 Data

Data used in the Pacific ocean perch assessment are summarized in Figure 2. A description of each data source is provided below.

2.1 Fishery-Independent Data:

2.1.1 Northwest Fisheries Science Center (NWFSC) shelf-slope survey

The NWFSC shelf-slope survey is based on a random-grid design; covering the coastal waters from a depth of 55 m to 1,280 m (Bradburn et al. 2011). This design uses four chartered industry vessels in most years, assigned to a roughly equal number of randomly selected grid cells. The survey, which has been conducted from late-May to early-October each year, is divided into two 2-vessel passes of the coast, which are executed from north to south. This design therefore incorporates both vessel-to-vessel differences in catchability as well as variance associated with selecting a relatively small number (approximately 700) of cells from a very large population of possible cells (greater than 11,000) distributed from the Mexican to the Canadian border.

The data from the NWFSC shelf-slope survey was analyzed using a spatio-temporal delta-model (Thorson et al. 2015), implemented as an R package VAST (Thorson and Barnett 2017) and publicly available online (https://github.com/James-Thorson/VAST). Spatial and spatio-temporal variation is specifically included in both encounter probability and positive catch rates, a logit-link for encounter probability, and a log-link for positive catch rates. Vessel-year effects were included for each unique combination of vessel and year in the database, to account for the random selection of commercial vessels used during sampling (Helser et al. 2004, Thorson and Ward (2014)). Spatial variation was approximated using 1000 knots, and use the bias-correction algorithm (Thorson and Kristensen 2016) in Template Model Builder (Kristensen et al. 2016). Further details regarding model structure are available in the user manual (https://github.com/James-Thorson/VAST/blob/master/examples/VAST_user_manual.pdf).

The smallest Pacific ocean perch tend to occur in the shallower depths (< 200 m) with only larger individuals occurring at depths deeper than 300 m. Data collected by the NWFSC shelf-slope survey between depths of 55 - 549 m and north of 42° and south of 49° were stratified to generate an index of abundance from 2003-2016. The estimated index of abundance is shown in Table 4. The lognormal distribution with random strata-year and vessel effects had the lowest AIC and was chosen as the final model. The Q-Q plot does not show any departures from the assumed distribution (Figure 4). The indices for the NWFSC shelf-slope survey show a tentative decline in the population between 2003 and 2009, with an increasing trend in biomass between the 2009 and 2016 median point estimates.

Length and conditional age-at-length compositions were expanded based upon the stratification. The number of tows with length data ranged from 33 in 2006 to 69 in 2015 (Table 5) where ages were collected for Pacific ocean perch in nearly every tow (Table 6). The expanded length frequencies from this survey show an increase in small fish starting in 2010 (Figure 5). The age frequencies provide clear evidence of large year-classes moving through the population from the 1999, 2000, and 2008 recruitment; with early indications of a large 2013 recruitment (Figure 6).

The effective sample sizes for length and marginal age composition data for all fishery-independent surveys were calculated according to Stewart & Hamel (2014) which determined that the approximate realized sample size for shelf/slope rockfish species was 2.43*N_{tow}. The effective sample size of conditional-age-at-length data was set at the number of fish at each length by year.

2.1.2 Northwest Fisheries Science Center (NWFSC) slope survey

The NWFSC slope survey covered waters throughout the summer from 183 m to 1280 m north of 34°30′ S, which is near Point Conception between 1999 and 2002. Tows conducted between the depths of 183 and 549 m were used to create an index of abundance using a bayesian delta-GLMM and the VAST delta-GLMM models. The estimated index of abundance is show in Table 4. Based on the diagnostics the bayesian delta-GLMM, which does not account for spatial effects, gamma distribution with year-vessel random effects was selected as the final model. The Q-Q plot does not show any extreme departures from the assumed distribution (Figure 7). The trend of abundance across the four surveys years was generally flat with high estimated annual variance.

Length and age compositions were available for 2001 and 2002 and were expanded based upon the survey stratification (Tables 7 and 8). The expanded length frequencies from this survey shows that primarily only large fish were captured both years (Figure 8). The majority of fish observed by this survey were aged at greater than 10 years (Figure 9).

The effective sample sizes for length and marginal age composition data were calculated according to Stewart & Hamel (2014) described in Section 2.1.1.

2.1.3 Alaska Fisheries Science Center (AFSC) slope survey

The AFSC slope survey operated during autumn (October-November) aboard the R/V Miller Freeman. Partial survey coverage of the US west coast occurred during 1988-96 and complete coverage (north of 34°30′ S) during 1997, 1999, 2000, and 2001. Only the four years of consistent and complete surveys plus 1996, which surveyed north of 43° N latitude to the US-Canada border, were used in this assessment. The number of tows with length data ranged from 19 in 2000 to 48 in 1996 (Table 9). Because a large number of positive tows occurred in 1996, it was decided to include that year, which surveyed from 43° N latitude to the US-Canada border. Therefore, only tows from 43° N latitude to the US-Canada border were used.

An index of abundance was estimated based on the data using the VAST delta-GLMM model. The estimated index of abundance is shown in Table 4. The lognormal distribution with random strata-year had the lowest AIC and was chosen as the final model. The Q-Q plot does not show any departures from the assumed distribution (Figure 10). The trend in the indices was generally flat over time.

Length compositions were available for each year the survey was conducted. No age data were available from this survey. The expanded length frequencies from this survey were generally of larger fish ($>$ 30 cm), expect for 1997 where the highest frequency of fish were between 20 and 30 cm for both females and males (Figure 11).

The effective sample sizes for length and marginal age composition data were calculated according to Stewart & Hamel (2014) described in Section 2.1.1.

2.1.4 Triennial Bottom Trawl Survey

The Triennial survey was first conducted by the AFSC in 1977 and spanned the time-frame from 1977-2004. The survey's design and sampling methods are most recently described in (Weinberg et al. 2002). Its basic design was a series of equally-spaced transects from which searches for tows in a specific depth range were initiated. The survey design has changed slightly over the period of time. In general, all of the surveys were conducted in the mid-summer through early fall: the 1977 survey was conducted from early July through late September; the surveys from 1980 through 1989 ran from mid-July to late September; the 1992 survey spanned from mid-July through early October; the 1995 survey was conducted from early June to late August; the 1998 survey ran from early June through early August; and the 2001 and 2004 surveys were conducted in May-July.

Haul depths ranged from 91-457 m during the 1977 survey with no hauls shallower than 91 m. The surveys in 1980, 1983, and 1986 covered the West Coast south to 36.8° N latitude and a depth range of 55-366 meters. The surveys in 1989 and 1992 covered the same depth range but extended the southern range to 34.5° N (near Point Conception). From 1995 through 2004, the surveys covered the depth range 55-500 meters and surveyed south to 34.5° N. In the final year of the Triennial series (2004), the NWFSC's Fishery Resource and Monitoring division (FRAM) conducted the survey and followed very similar protocols as the AFSC.

Given the different depths surveyed during 1977, the data from that year were not included in this assessment. Water hauls (Zimmermann et al. 2003) and tows located in Canadian waters were also excluded from the analysis of this survey. The data was examined for varying distribution of length and/or ages of fish based upon the shift in survey timing and little evidence was found of ontogenetic shifts in Pacific ocean perch during the summer months. Pacific ocean perch are rarely encountered south of 40° where the change in southern range of the survey would have no impact on data collected regarding Pacific ocean perch. Given these factors the Triennial survey was analyzed as a single time-series, a departure from how the previous assessment which split the time-series into and an early (1980-1992) and a late period (1995-2004).

An index of abundance was estimated based on the data using the VAST delta-GLMM model. The estimated index of abundance is shown in Table 4. The lognormal distribution with random strata-year had the lowest AIC and was chosen as the final model. The Q-Q plot does not show any departures from the assumed distribution (Figure 12). The index shows a decline in abundance in the early years of the time-series and abundance remaining flat for the latter years.

Length and age compositions were expanded based upon the stratification. The number of tows with length data ranged from 17 in 1986 to 81 in 1998 (Table 10). Ages were read using surface reading methods until 1989 when the break-and-burn method replaced surface reads as the best method to age Pacific ocean perch. Unfortunately, surface reading of Pacific ocean perch otoliths results in significant underestimates of age. Due to this, these otoliths were excluded from analysis. The available ages from the Triennial survey and the number of tows where otoliths were collected are shown in Table 11. The expanded length frequencies from this survey show an increase in small fish starting in 1995 (Figure 13). The age frequencies provide clear evidence of large year-classes moving through the population from the 1999 and 2000 recruitment (Figure 14).

The effective sample sizes for length and marginal age composition data were calculated according to Stewart & Hamel (2014) described in Section 2.1.1.

2.1.5 Pacific ocean perch Survey

A survey designed to sample Pacific ocean perch was conducted in 1979 and again in 1985 (for a detailed description see (Ianelli et al. 1992)). An index of abundance was estimated based on the data using the VAST delta-GLMM model. The estimated index of abundance is shown in Table 4. The lognormal distribution with random strata-year had the lowest AIC and was chosen as the final model. The Q-Q plot does not show any departures from the assumed distribution (Figure 15). The index shows a clear decline in abundance between the two survey years.

Length and age compositions were expanded based on the stratification. The survey had 125 and 126 Pacific ocean perch tows (Table 12) and ages were only available in 1985 due to surface reads for the 1979 data (Table 13). The length frequencies for both years are highest between the 30-45 cm range (Figure 16) with ages in 1985 having a large number of fish age 40 and greater (Figure 17).

The effective sample sizes for length and marginal age composition data were calculated according to Stewart & Hamel (2014) described in Section 2.1.1.

2.2 Fishery-Dependent Data

2.2.1 Commercial Fishery Landings

Washington

Historical commercial fishery landings of Pacific ocean perch from Washington for the years 1908-2016 were obtained from Theresa Tsou (WDFW) and Phillip Weyland (WDFW). This assessment is the first Pacific ocean perch assessment to include a state provide historical catch reconstruction and hence, the historical catches for Washington differ from those used in the 2011 assessment. Due to recent corrections to the landings of Pacific ocean perch based upon market categories (1981-2016) were obtained directly from Washington state rather than from Pacific Fisheries Information Network (PacFIN).

Oregon

Historical commercial fishery landings of Pacific ocean perch from Oregon for the years 1892-1986 were obtained from Alison Dauble (ODFW). A description of the methods can be found in Karnowski et al. (2014). Recent landings (1987-2016) were obtained from PacFIN retrieval dated May 2, 2017, Pacific States Marine Fisheries Commission, Portland, Oregon; www.psmfc.org). The catch data in from the POP and POP2 categories contained within PacFIN for Pacific ocean perch were used for this assessment. Additional catches from 1987-1999 for Pacific ocean perch under the UROCK category not yet available in PacFIN were received directly from the state and combined with the catch data available for that period within PacFIN (Patrick Mirrick, personal communication, ODFW).

California

Historical commercial fishery landings of Pacific ocean perch were obtained directly from John Field at the SWFSC due to database issues for the historical period for the California Cooperative Groundfish Survey, also known as CALCOM (128.114.3.187) for the years 1916-1980. A description of the historical reconstruction methods can be found in (Ralston et al. 2010). Recent landings (1981-2016) were obtained from PacFIN retrieval dated May 2, 2017, Pacific States Marine Fisheries Commission, Portland, Oregon; www.psmfc.org).

At-Sea Hake Fishery

Catches of Pacific ocean perch are monitored aboard the vessel by observers in the At-Sea hake Observer program (ASHOP) and were available for the years of 1975-2016. Observers use a spatial sample design, based on weight, to randomly choose a portion of the haul to sample for species composition. For the last decade, this is typically 30-50% of the total weight. The total weight of the sample is determined by all catch passing over a flow scale. All species other than hake are removed and weighed by species on a motion compensated flatbed scale. Observers record the weights of all non-hake species. Non-hake species total weights are expanded in the database by using the proportion of the haul sampled to the total weight of the haul. The catches of non-hake species in unsampled hauls is determined using bycatch rates determined from sampled hauls. Since 2001, more than 97% of the hauls have been observed and sampled.

Foreign Catches

From the 1960s through the early 1970s, foreign trawling enterprises harvested considerable amounts of rockfish off Washington and Oregon, and along with the domestic trawling fleet, landed large quantities of Pacific ocean perch. Foreign catches of individual species were estimated by Rogers (2003) and attributed to INPFC areas for the years of 1966-1976 for

Pacific ocean perch. The foreign catches were combined across areas for a coastwide removal total.

2.2.2 Discards

Data on discards of Pacific ocean perch are available from two different data sources. The earliest source is referred to as the Pikitch data and comes from a study organized by Ellen Pikitch that collected trawl discards from 1985-1987 (Pikitch et al. 1988). The northern and southern boundaries of the study were $48°42'$ N latitude and $42°60'$ N. latitude respectively, which is primarily within the Columbia INPFC area (Pikitch et al. 1988 , Rogers and Pikitch 1992). Participation in the study was voluntary and included vessels using bottom, midwater, and shrimp trawl gears. Observers of normal fishing operations on commercial vessels collected the data, estimated the total weight of the catch by tow and recorded the weight of species retained and discarded in the sample. Results of the Pikitch data were obtained from John Wallace (personal communication, NWFSC, NOAA) in the form of ratios of discard weight to retained weight of Pacific ocean perch and sex-specific length frequencies. Discard estimates are shown in Table 14.

The second source is from the West Coast Groundfish Observer Program (WCGOP). This program is part of the NWFSC and has been recording discard observations since 2003. Table 14 shows the discard ratios (discarded/(discarded + retained)) of Pacific ocean perch from WCGOP. Since 2011, when the trawl rationalization program was implemented, observer coverage rates increased to nearly 100% for all the limited entry trawl vessels in the program and discard rates declined compared to pre-2011 rates. Discard rates were obtained for both the catch-share and the non-catch share sector for Pacific ocean perch. A single discard rate was calculated by weighting discard rates based on the commercial landings by each sector. Coefficient of variations were calculated by bootstrapping vessels within ports because the observer program randomly chooses vessels within ports to be observed in the non-catch shares sectors. Discard length composition for the trawl fleet varied by year, with larger fish being discarded prior to 2011 (Figure 18).

2.2.3 Historical Commercial Catch-per-unit effort

Data on catch-per-unit-effort (CPUE) in mt/hr from the domestic fishery were combined for the INPFC Vancouver and Columbia areas (Table 15, from Gunderson (1977)). Although these data reflect catch rates for the US fleet, the highest catch rates coincided with the beginning of removals by the foreign fleet. This suggest that, barring unaccounted changes in fishing efficiency during this period, the level of abundance was high at that time. A CV of 0.40 was used in this assessment to be consistent with the CV observed in the survey data.

2.2.4 Fishery Length And Age Data

Biological data from commercial fisheries that caught Pacific ocean perch were extracted from PacFIN on May 4, 2017. Lengths taken during port sampling in Oregon and Washington were used to calculate length and age compositions. There were no biological data from California for Pacific ocean perch available within PacFIN. The overwhelming majority of these data were collected from the mid-water and bottom trawl gear, but additional biological data were collected from non-trawl gear which was grouped together with trawl gear data. Tables 16 and 17 show the number of trips and fish sampled, along with the calculated sample sizes. Length and age data were acquired at the trip level, and then aggregated to the state level. The sample sizes were calculated via the Stewart Method (Ian Stewart, personal communication, IPHC):

$$\text{Input effN} = N_{\text{trips}} + 0.138 * N_{\text{fish}} \text{ if } N_{\text{fish}}/N_{\text{trips}} \text{ is} < 44$$

$$\text{Input effN} = 7.06 * N_{\text{trips}} \text{ if } N_{\text{fish}}/N_{\text{trips}} \text{ is} \geq 44$$

The fishery fleet observed Pacific ocean perch that were generally greater than 30 cm across all years of available data (Figure \ref{fig:Comm_Length). The fishery fleet age data has clear trends of a large cohort moving through the population (Figure 20). Lengths and ages were also available for the At-sea hake fishery and are shown in Figures 21 and 22.

2.3 Biological Data

2.3.1 Natural mortality

Historic Pacific ocean perch ages determined using scales and surface reading methods of otoliths, resulted in estimates of natural mortality (M) of between 0.10 and 0.20yr^{-1} with a longevity less than 30 years(Gunderson 1977). Based on break-and-burn method of age determination using otoliths, the maximum age of Pacific ocean perch was revised to be 90 years (Chilton and Beamish 1982). The updated understanding concerning Pacific ocean perch longevity reduced the estimate of natural mortality based on Hoenig's (1983) relationship to 0.059yr^{-1}. The previous assessment applied a prior distribution on natural mortality based upon multiple life history correlates (including Hoenig's method, Gunderson gonadosomatic index (1997), and McCoy and Gillooly's (2008) theoretical relationship) developed separately for female and male Pacific ocean perch.

Hamel (2015) developed a method for combining meta-analytic approaches relating the natural mortality rate M to other life-history parameters such as longevity, size, growth rate and reproductive effort, to provide a prior on M. In that same issue of ICESJMS, Then et al. (2015), provided an updated data set of estimates of M and related life history parameters across a large number of fish species, from which to develop an M estimator for fish species in general. They concluded by recommending M estimates be based on maximum age alone, based on an updated Hoenig non-linear least squares (nls) estimator $M = 4.899 A_m ax^(-.916)$. The approach of basing M priors on maximum age alone was one that was already being used for West Coast rockfish assessments. However, in fitting the alternative model forms relating M to $A_{\max}$, Then et al. (2015) did not consistently apply their transformation. In particular, in real space, one would expect substantial heteroscedasticity in both the observation and process error associated with the observed relationship of M to $A_{\max}$. Therefore, it would be reasonable to fit all models under a log transformation. This was not done. Re-evaluating the data used in Then et al. (2015) by fitting the one-parameter $A_{\max}$ model under a log-log transformation (such that the slope is forced to be -1 in the transformed space (Hamel 2015)), the point estimate for M is:

$$M = \frac{5.4}{A_{\max}}$$

The above is also the median of the prior. The prior is defined as a lognormal with mean $ln(\frac{5.4}{A_{\max}})$ and SE = 0.438. Using a maximum age of 100 the point estimate and median of the prior is 0.054. The maximum age was selected based on available age data from all West Coast data sources. The oldest aged rockfish was 120 years, captured by the commercial fishery in 2007. However, age data are subject to ageing error which could impact this estimate of longevity. The selection of 100 years was based on the range of other ages available with had multiple observations of fish between 90 and 102 years of age.

2.3.2 Sex ratio, maturation, and fecundity

Examining all biological data sources, the sex ratio of young fish are within 5% of 1:1 by length until larger sizes which are dominated by females who reach a larger maximum size relative to males (Figure 23), with the sex ratio being approximately equal across ages (Figure 24), and hence this assessment the sex ratio at birth was assumed to be 1:1. This assessment assumed a logistic maturity-at-length curve based on analysis of 537 fish maturity samples collected from the NWFSC shelf-slope survey. This is revised from the previous assessment which assumed maturity-at-age based on the work of Hannah and Parker (2007). Additionally, the new maturity-at-length curve is based on the estimate of functional maturity, an approach that classifies rockfish maturity with developing oocytes as mature or immature based on the proportion of vitellogenin in the cytoplasm and the measured frequency of atretic cells (Melissa Head, personal communication, NWFSC, NOAA). The 50% size-at-maturity was estimated at 32.1 cm with maturity asymptoting to 1.0 for larger fish (Figure 25). Comparison between the maturity-at-age used in the previous assessment and the updated functional maturity-at-length is shown in Figure 26.

The fecundity-at-age has also been updated from the previous assessment based on new research. Dick (2017) estimated new fecundity relationships for select West Coast stocks where fecundity for Pacific ocean perch was estimated equal to 8.66e-10$L^{4.98}$ in millions of eggs. Spawning output at length is shown in Figure 27.

2.3.3 Length-weight relationship

The length-weight relationship for Pacific ocean perch was estimated outside the model using all biological data available from fishery-dependent and -independent data sources where the female weight-at-length in grams was estimated at 1.044e-05$L^{3.09}$ and males at 1.05e-05$L^{3.08}$ where L is length in cm (Figures 28 and 29).

2.3.4 Growth (length-at-age)

The length-at-age was estimated for male and female Pacific ocean perch using data collected from both fishery-dependent and -independent data sources that were collected from 1981-2016. Figure 30 shows the lengths and ages for all years and all data as well as predicted von Bertalanffy fits to the data. Females grow larger than males and sex specific growth parameters were estimated at the following values:

$$\text{Females } L_\infty = 42.32;\ k = 0.169;\ t_0 = \text{-}1.466$$

$$\text{Males } L_\infty = 39.03;\ k = 0.212;\ t_0 = \text{-}1.02$$

These values were used as starting parameter values within the model prior to estimating each parameter for male and female Pacific ocean perch.

2.3.5 Ageing Precision And Bias

Uncertainty surrounding the ageing error process for Pacific ocean perch was incorporated by estimating ageing error by age. Age-composition data used in the model were from break-and-burn otolith reads aged by the Cooperative Ageing Project (CAP) in Newport, Oregon. Break-and-burn double reads of more than 1500 otoliths were provided by the CAP lab. An ageing error estimate was made based on these double reads using a computational tool specifically developed for estimating ageing error (Punt et al. 2008), and using release 1.0.0 of the R package nwfscAgeingError (Thorson et al. 2012) for input and output diagnostics, publicly available at: https://github.com/nwfsc-assess/nwfscAgeingError. A non-linear standard error was estimated by age where there is more variability in the age of older fish (Table 20 and Figure 31).

2.4 History Of Modeling Approaches Used For This Stock

2.4.1 Previous Assessments

The status of Pacific ocean perch off British Columbia, Washington, and Oregon have been periodically assessed since the intensive exploitation that occurred in the 1960s. Concerns regarding Pacific ocean perch status off the coast the US west coast were raised in the late 1970s (Gunderson 1978, 1981) and in 1981 the PFMC adopted a 20-year plan to rebuild the stock.

The 1992 assessment determined that Pacific ocean perch remained at low levels relative to the population size in 1960 (Ianelli et al. 1992) and recommended additional harvest restrictions to allow for stock rebuilding. The 1998 assessment (Ianelli and Zimmermann 1998) estimated that the stock was 13% of the unfished level, leading the National Marine Fishery Service (NMFS) to declare the stock overfished in 1999. A formal rebuilding plan was implemented in 2001. The rebuilding plan reduced the SPR harvest rate used to determine catches to 0.864 (in contrast to the default harvest rate of 0.50). The last full assessment of Pacific ocean perch was conducted in 2011 (Hamel and Ono 2011) which concluded that the stock was still well below the target biomass of $40\% SB_0$ estimating the relative stock status at 19.1%.

2.4.2 Previous Assessment Recommendations

Recommendation: Considering trans-boundary stock effects should be pursued. In particular the consequences of having spawning contributions from external stock components should be evaluated relative to the steepness estimates obtained in the present assessment.

STAT response: The STAT team agrees that this should be an ongoing area of research and collaboration between the US and Canada. This assessment presents a sensitivity where the inclusion of Canadian data are included within the model.

Recommendation: The benefits of adopting the complex model used this year should be evaluated relative to simpler assumptions and models. While the transition from the simpler old model to Stock Synthesis was shown to be similar for the historical period, the depletion estimates in the most recent years were different enough to warrant further investigation.

STAT response: This assessment was performed in Stock Synthesis, an integrated model, which can be modified to either simple or complex structural forms based upon the available data and the processes being modeled. There were not addtional explorations of alternative modeling platforms.

Recommendation: Discard estimates from observer programs should be presented, reviewed (similar to the catch reconstructions), and be made available to the assessment process.

STAT response: This assessment uses discard rates and discard lengths collected by the WCGOP from 2003-2015.

Recommendation: The ability to allow different “plus groups” for specific data types should be evaluated (and implemented in Stock Synthesis). For example, this would provide the ability to use the biased surface-aged data in an appropriate way.

STAT response: Additional research needs to completed which evaluates the amount of bias and imprecision in surface-read ages. Evaluating available surface-read ages within the PacFIN database fish of lengths between 23-44 cm can be aged at 10 years old. This large range of lengths at the same age indicates considerable bias in ages for fish surface-read younger aged fish.

Recommendation: Historical catch reconstruction estimates should be formally reviewed prior to being used in assessments and should be coordinated so that interactions between stocks are appropriately treated. The relative reliability of the catch estimates over time could provide an axis of uncertainty in future assessments.

STAT response: California and Oregon have undergone extensive work to create historical catch reconstructions. This is the first assessment for Pacific ocean perch which includes a Washington historical catch reconstruction. The data used in this assessment represent Washington state's current best estimate for historical catches. Both California and Washington are conducting research to estimate uncertainty surround historical catches which could be used to propegate uncertainty within the assessment.

3 Assessment

3.1 General Model Specifications and Assumptions

Stock Synthesis v3.30.03.05 was used to estimate the parameters in the model. R4SS, revision 1.27.0, along with R version 3.3.2 were used to investigate and plot model fits. A summary of the data sources used in the model (details discussed above) is shown in Figure 2.

Stock Synthesis has many options when setting up a model and the assessment model for Pacific ocean perch was set up in the following manner.

3.1.1 Changes between the 2011 assessment model and current model

The current model for Pacific ocean perch has many made many similar assumptions to the 2011 assessment but differs in some key ways. This assessment disaggregated the fleets into a trawl/other gear, At-sea hake, historical foreign fleet, and research fleets. The previous assessment implemented a single fleet where removal from all sources were aggregated together. The separating of fleets applied in this assessment allowed for differing assumptions regarding current and historical discarding practices. Although there are no compositional data available from the foreign fleet, it is assumed that very little discarding to no discarding of fish occurred. Additionally, the At-sea hake fishery removals are represent both discarded and retained fish and hence an additional discard rate would not be appropriate. Similar logic was applied in regard to survey removals.

The historical landings used in the model differs from those used in 2011. The assessment includes the first state provided historical reconstruction landings for Washington state. The historical reconstruction has removals starting in 1916 and have larger removals in the 1940s relative to those used in 2011 (Figure 32). Given the increase in historical removals prior to 1940, the 2011 model starting year, the starting year for modeling the stock was revised to 1918, the first year Pacific ocean perch landings exceeded 1 mt. Explorations were conducted relative to the model starting year and no differences were found between the 1918 start year compared to starting the model in 1892, the first record of Pacific ocean perch landings between California, Oregon, and Washington catch data.

Selectivity in this model is assumed to be length-based and is modeled using double-normal for all fleets, expect the Pacific ocean perch survey which retained the previous assessment assumption of logistic selectivity. The previous assessment mirrored selectivity among the Pacific ocean perch and both slope surveys (AFSC and NWFSC). This assessment allows for survey specific selectivity.

All fishery-independent indices have been reevaluated for this assessment using a spatial-temporal delta generalized linear mixed model (VAST delta-GLMM) which is updated approach from that used 2011 which did not incorporate spatial effects. An additional update to the treatment of survey data was the decision to use the Triennial survey as a single time-series ranging from 1980-2004. The previous assessment opted to split this survey into an early and a late index of abundance based upon the change in southern sampling and a shift in survey timing. Northern California is considered to be the southern end of Pacific ocean perch West Coast distribution with rare encounters in central or southern California waters. The biological data from the Triennial survey showed no discernible ontogenetic shifts in Pacific ocean perch during the early or late period of summer samples. Based upon these investigations, the Triennial survey was retained as a single index of abundance.

Maturity and fecundity were updated for this assessment based upon new research. Fecundity for Pacific ocean perch used in this assessment was base on a reevaluation of the fecundity of West Coast rockfish by Dick et al. (2017), updating the previous fecundity estimates used in the 2011 assessment (Dick 2009) (Figure 27). Maturity in this assessment was based on examination of 537 fish samples which were used to estimate functional maturity, an approach that classifies rockfish maturity with developing oocytes as mature or immature based on the proportion of vitellogenin in the cytoplasm and the measured frequency of atretic cells (Melissa Head, personal communication, NWFSC, NOAA). The updated maturity curve was based on maturity-at-length where the previous estimates used in 2011 were based on maturity-at-age (Figure 26).

In this assessment, the beta prior developed from a meta-analysis of West Coast groundfish was updated to the 2017 value (J. Thorson, pers comm, NWFSC, NOAA) in preliminary models, with steepness fixed at an alternative value in the final base model. Additionally, the prior for natural mortality was updated based on analysis conducted by Owen Hamel (personal communication, NWFSC, NOAA), where female and male natural mortality fixed at the prior median.

3.1.2 Summary of Fleets and Areas

Pacific ocean perch are most frequently observed in Oregon and Washington waters in survey and fishery observations. Multiple fisheries encounter Pacific ocean perch. Trawl, fixed gear, and the At-sea (mid-water) hake fisheries account for the majority of the current Pacific ocean perch landings.

The majority of removals of Pacific ocean perch were observed by the trawl gears with fixed gear accounting for a small fraction of the catches available within PacFIN. Trawl and fixed gears were combined into a coast-wide fleet. For the period from 1918 to the early 1990s, prior to the introduction of trip limits for rockfish, limited discarding of Pacific ocean perch was assumed. Observations of Pacific ocean perch in the Pikitch et al. (1988) data (1986-1987) allowed for a formal analysis of discard rates which were applied to the historical period of the fishery. Foreign trawl catches (1966-1976) were modeled as a single fleet. The At-sea hake fishery operates as a mid-water fishery targeting Pacific whiting but encounters Pacific ocean perch as a bycatch species. This fleet was also modeled as a single fleet.

3.1.3 Other Specifications

The specifications of the assessment are listed in Table 21. The model is a two-sex, age-structured model starting in 1918 with an accumulated age group at 60 years. Growth was estimated and natural mortality was fixed at the median of the prior. The lengths in the population were tracked by 1 cm intervals and the length data were binned into 1 cm intervals. A curvilinear ageing imprecision relationship was estimated and used to model ageing error. Fecundity-at-length was fixed at the values from Dick et al. (2017) for Pacific ocean perch and spawning output was defined in millions of eggs.

Age data were available for the commercial and At-sea hake fishery, as well as the Triennial, the Pacific ocean perch, the NWFSC slope, and the NWFSC shelf-slope surveys. The ages from the NWFSC shelf-slope survey and were entered into the model as conditional age-at-length. The assessment used length-frequencies collected by the fishery fleet, the At-sea hake fishery, the Triennial, Pacific ocean perch, AFSC slope, NWFSC slope, and the NWFSC shelf-slope surveys.

The specification of when to estimate recruitment deviations is an assumption that likely affects model uncertainty. It was decided to estimate recruitment deviations from 1900-2014 to appropriately quantify uncertainty. The earliest length-composition data occur in 1966 and the earliest age data were in 1981. The most informed years for estimating recruitment deviations were from about the mid-1970s to about 2011. The period from 1900-1974 was fit using an early series with little or no bias adjustment, the main period of recruitment deviates occurred from 1975-2014 with an upward and downward ramping of bias adjustment, and 2015 onward was fit using forecast recruitment deviates with little bias adjustment. Methot and Taylor (2011) summarize the reasoning behind varying levels of bias adjustment based on the information available to estimate the deviates. The standard deviation of recruitment variability was assumed to be 0.70.

The recommended selectivity type in Stock Synthesis is the double normal and was used in this assessment for the all fleets, except the Pacific ocean perch survey which was assumed logistic based on the length composition data. Changes in retention curves were estimated for the commercial fishery fleet.

Time blocks for the fishery fleet are provided in Table 21. Fishery retention has changed over the modeled period due to management changes. The time block on the retention curves for the fishery were set from 1918-1991, 1992-2001, 2002-2007, 2008, 2009-2010, 2011-2016 based on available discarding data and changes in trip limits that likely resulted in changes to discarding patterns of Pacific ocean perch. No discarding was assumed in the At-sea hake and the foreign fisheries.

The following distributions were assumed for data fitting. Survey indices were lognormal, total discards were lognormal.

3.1.4 Modeling Software

The STAT team used Stock Synthesis version 3.30.03.05 by Dr. Richard Methot at the NWFSC (Methot and Wetzel 2013). This most recent version was used, since it included improvements and corrections to older versions. The previous assessment of Pacific ocean perch also used Stock Synthesis but a earlier version, 3.24, model bridging was performed between both versions of Stock Synthesis and are shown in Figure 33.

3.1.5 Priors

A prior distribution was developed for natural mortality (M) from an analysis based on an assumed maximum age of 100 years. The analysis was performed by Owen Hamel (personal communications, NWFSC, NOAA) and used data from Then et al. (2015) to provide a lognormal distribution for natural mortality. The median of the lognormal prior is 0.054 and has a standard error of 0.438.

The prior for steepness (h) assumes a beta distribution with parameters based on an update of the Thorson-Dorn rockfish prior (commonly used in past West Coast rockfish assessments) conducted by James Thorson (personal communication, NWFSC, NOAA) which was reviewed and endorsed by the Science and Statistical Committee in 2017. The prior is a beta distribution with μ=0.72 and σ=0.15. However, fixing steepness within the model resulted in what was determined to be unrealistic relative biomass levels (> 1), and it was decided to fix steepness at 0.50. The previous assessment estimated and fixed steepness equal to 0.40. The current data does not contain information regarding steepness and 0.50 was selected as an intermediate value between the prior and the previous assessment value. The steepness value of 0.50 was contained within the estimated uncertainty envelope from the assessment model when either the prior value of 0.72 or 0.40 values were assumed.

3.1.6 Data Weighting

The base case was weighted such that the various data sources were mostly consistent with each other in terms of the relationship between input and effective sample sizes. Length and age-at-length compositions from the NWFSC shelf-slope survey were fit along with length and marginal age compositions from the fishery and other survey fleets. Length data started with a sample size determined from the equation listed in 2.1.1 (survey data) and Section 2.2.4 (fishery data). Age-at-length data assumed that each age was a random sample within the length bin and started with a sample size equal to the number of fish in that length bin. However, the 2016 NWFSC shelf-slope age-at-length data was variable compared to previous years for both males and females relative to all other years with observed fish being larger at age. Due to the increased variability within this data year, the effective sample size for this year was reduced to 50% of the number of fish within each length-age bin.

One extra variability parameter was estimated and added to the input variance for the Triennial and the NWFSC shelf-slope survey indices. Estimating additional variance for the CPUE and other surveys were explored and determined to not be required. Vessels present in the WCGOP data were bootstrapped to provide uncertainty of the total discards (Table 14).

The base case assessment model was weighted using the "Francis method", which was based on equation TA1.8 in Francis (2011). This formulation looks at the mean length or age and the variance of the mean to determine if across years, the variability is explained by the model. If the variability around the mean does not encompass the model predictions, then that data source should be down-weighted. This method does account for correlation in the data (i.e., the multinomial distribution) as opposed to the McAllister and Ianelli (1997) method of looking at the difference between individual observations and predictions.

3.1.7 Estimated And Fixed Parameters

There were 164 estimated parameters in the base case model. These included one parameter for R_0, 8 parameters for growth, 2 parameters for extra variability on the Triennial and NWFSC shelf-slope surveys indices, 24 parameters for selectivity, retention, and time blocking of the fleets and the surveys, 117 recruitment deviations, and 12 forecast recruitment deviations (Table 23).

Fixed parameters in the model were as follows. Steepness was fixed at 0.50. A sensitivity analysis and a likelihood profile were done for steepness. Natural mortality was fixed at 0.054 for females and males, which is the median of the prior. The standard deviation of recruitment deviates was fixed at 0.70. Maturity-at-length was fixed as described in Section 2.3.2. Length-weight parameters were fixed at estimates using all length-weight observations (Figure 29).

Dome-shaped selectivity was explored for all fleets within the model. Older Pacific ocean perch are often found in deeper waters and may move into areas that limit their availability to fishing gear, especially trawl gear. Domed shape selectivity was determined to provide the best fit to the data for the fishery fleet and the Triennial survey. The final base model assumed asymptotic selectivity for the At-sea hake fishery, and all other surveys.

3.2 Model Selection and Evaluation

The base case assessment model for Pacific ocean perch was developed to balance parsimony and realism, and the goal was to estimate a biomass trajectory for the population of Pacific ocean perch on the west coast of the US. The model contains many assumptions to achieve parsimony and uses many different sources of data to estimate reality. A series of investigative model runs were done to achieve the final base case model.

3.2.1 Key Assumptions and Structural Choices

The key assumptions in the model were that the assessed population is a single stock with biological parameters characterizing the entire coast, maturity at age has remained constant over the period modeled, weight-at-length has remained constant over the period modeled, the standard deviation in recruitment deviation is 0.70, and steepness is 0.50. These are simplifying assumptions that unfortunately cannot be verified or disproved. Sensitivity analyses were conducted for most of these assumptions to determine their effect on the results.

Structurally, the model assumed that the catches from each fleet were representative of the coastwide population, instead of specific areas, and fishing mortality prior to 1918 was negligible. It also assumed that discards were low prior to 1992 and after 2010.

3.2.2 Alternate Models Considered

The exploration of models began by bridging from the 2011 assessment to Stock Synthesis version 3.30.03.05, which produced no discernible difference. The updated catch series with discards added per the 2011 assessment produced insignificant differences in the relative scale of the population although the updated historical removals resulted in an increase in the estimate of unfished biomass. Updating the survey indices produced small differences in the relative scale of the population. Adding age and length data each resulted in less of a population decline from the 1970s to pre-2000, resulting in an increase in the estimated final stock status as of 2016. However, the addition of new data resulted in an early pattern within recruitment, indicating that the assumptions within the previous model may not represent the best fit to the current data.

This assessment estimated discards in the model, so time was spent investigating time blocks for changes in selectivity and retention to match the limited discard data as best as possible. Using major changes in management and observed changes in landings, a set of blocks for retention was found for the bottom trawl fleets. In the spirit of parsimony, we used as few blocks as possible, allowed blocks only for time periods with data, and added new blocks when we felt they were justified by changes in management and they improved the fit to the data.

Natural mortality was also investigated and a new prior was developed assuming a maximum age of 100 years for females and males. The previous assessment estimated male natural mortality as an offset from female natural mortality which was fixed at the median of the 2011 prior (0.05). This assessment attempted to estimate natural mortality for both sexes using the 2017 updated prior, but there was little to no information on natural mortality within the data and hence opted to fix the value for females. Upon additional exploration, the model estimated very little difference in male natural mortality relative to females ($<$ 0.002) and in the interest of selecting the model that fit the data with the fewest parameters required, males were fixed equal to the female natural mortality.

Finally, multiple models were investigated where steepness was either estimated, fixed at the prior, or at an alternate value. The assessment in 2011 determined that there was sufficient information concerning steepness where the parameter was estimated and then fixed at 0.40. Based upon likelihood profiles performed on the current assessment, there was no longer support for a steepness value of 0.40 and the likelihood profile was flat across various levels of steepness with a very small improvement in likelihood ($<$0.50 log likelihood units) at the lowest steepness values. Estimating steepness starting at the median of the "type C" prior, the meta-analysis prior evaluated omitting information from Pacific ocean perch, of 0.76 resulted in very little if any movement from the median value due to the flat likelihood surface across values for this parameter with final relative stock status for 2017 being estimated to $>$ 100% of unfished biomass. Fixing steepness at the median of the prior of 0.72 resulted in relative stock status estimates for 2017 at 98.6% of unfished biomass. It was determined that the resulting stock status estimates when steepness was fixed at the meta-analysis prior were overly optimistic and unrealistic given the biology and historical exploitation of Pacific ocean perch.

3.2.3 Convergence

Proper convergence was determined by starting the minimization process from dispersed values of the maximum likelihood estimates to determine if the model found a better minimum. This was repeated 100 times and a better minimum was not found (Table 22). The model did not experience convergence issues when provided reasonable starting values. Through the jittering done as explained above and likelihood profiles, we are confident that the base case as presented represents the best fit to the data given the assumptions made. There were no difficulties in inverting the Hessian to obtain estimates of variability, although much of the early model investigation was done without attempting to estimate a Hessian.

3.3 Response To The Current STAR Panel Requests

TBD after the STAR panel.

3.4 Base Model Results

The base model parameter estimates along with approximate asymptotic standard errors are shown in Table 23 and the likelihood components are shown in Table 24. Estimates of derived reference points and approximate 95% asymptotic confidence intervals are shown in Table 25. Time-series of estimated stock size over time are shown in Table 26.

3.4.1 Parameter Estimates

The estimates of maximum length and the von Bertanlaffy growth coefficient, k, were less than the the external estimates for males and females (Figure 30), but were well within the 95% confidence interval given the estimated uncertainty (Table 23 and Figure 34). Female and male Pacific ocean perch grow quickly at younger ages, reaching near maximum length by age 20, with female Pacific ocean perch reaching larger maximum lengths.

Selectivity curves were estimated for commercial and survey fleets. The estimated selectivity for all fleets within the model are shown in Figure 35. The fishery selectivity was estimated dome shaped, reaching maximum selectivity for fish between 35 and 40 cm. The At-sea hake fishery was estimated to have little selectivity for smaller Pacific ocean perch and only reaching full selectivity at the largest sizes. Survey selectivities, excluding the Triennial survey, were estimated asymptotic during model explorations with the final selectivity fixed asymptotic in the final base model. The Triennial survey selectivity peaked at lengths between 25 and 30 cm and declined before reaching a constant selectivity for larger Pacific ocean perch. The foreign fleet for which only catch data are available was assumed to be identical to the main fishery, although a sensitivity was performed (not shown) that mirrored the foreign selectivity to that of the Pacific ocean perch survey selectivity resulting in a negligible difference in stock status.

Retention curves were estimated for the fishery fleet only and were allowed to vary based upon discard data within the model over time (Figure 36). Historical retention was estimated high and declined over time due to management restriction on landings of Pacific ocean perch with the lowest retention occurring in 2009 and 2010 prior to the implementation of ITQs. Post-2011 retention was estimated to be nearly 100% for the fishery fleet.

Additional survey variability (process error added directly to each year's input variability) for the Triennial and the NWFSC shelf-slope surveys were estimated within the model. The estimated added variance for the Triennial survey was high at 0.39. The model estimated a small added variance for the NWFSC shelf-slope survey of 0.03. Preliminary models explored estimating added variance for each of the other indices, but resulted in no added variance being estimated and hence were not estimated in the base model.

Estimates of recruitment suggest that the Pacific ocean perch population is characterized by variable recruitment with occasional strong recruitments and periods of low recruitment (Figures 37 and 38). There is little information regarding recruitment prior to 1970 and the uncertainty in those estimates is expressed in the model. The four lowest recruitments (in ascending order) occurred in 2012, 2003, 1998, and 2005. There are very large, but uncertain, estimates of recruitment in 2008, 2013, 2000, and 1999. The 2008 recruitment event is estimated to be larger by an order of magnitude than any other recruitment estimated in the model. The uncertainty interval in number of recruits is large based on the uncertainty surrounding the spawning output in that year. However, the log recruitment deviation estimated uncertainty is low.

3.4.2 Fits to the Data

There are numerous types of data for which the fits are discussed: fishery CPUE index, survey abundance indices, discard data (biomass and length compositions), length composition data for the fisheries and surveys, marginal age compositions for the fisheries and surveys, and conditional age-at-length observations for the NWFSC shelf-slope survey

The fits the fishery CPUE and five survey indices are shown in Figure 39. Extra standard error was estimated for the Triennial and NWFSC shelf-slope surveys. The fishery CPUE and Pacific ocean perch survey index were fit well by the model. The first two years of the Triennial survey index, 1980 and 1983, were much higher than the later years and were poorly fit by the model. Both the AFSC and NWFSC slope survey indices were generally flat and fit well by the model. The recent NWFSC shelf-slope survey showed a variable trend over the time period with the 2016 data point being the highest estimate of the series and given the uncertainty around each data point the model fit the model fit fell with the uncertainty interval for all years.

Fits to the total observed discard amounts required time blocks (Figure 40). Fits to the trawl discards from the Pikitch data in 1985-1987 were quite good. Discard rate change modeled over the 1992 - 2001 was based on management restrictions which were assumed to have increased discarding practices in the fishery fleet. The next required time block was based on the WCGOP data from 2002-2007 and were fit well by the model. Discarding increased prior to the implementation to ITQs requiring blocks for 2008 and the 2009-2010 periods. The model fit the very low post-ITQ discard rates based on the WCGOP data well.

Fits to the length data are shown based on the proportions of lengths observed by year and the Pearson residuals-at-length for all fleets. Detailed fits to the length data by year and fleet are provided in Appendix 10. Aggregate fits by fleet are shown in Figure 41. There are a few things that stand out when examining the aggregated length composition data. First, the sexed discard lengths appear to be poorly fit by the model but this is related to small sample sizes. The NWFS slope survey lengths were under estimated by the model, but these data are over only two years. Finally, both the Triennial and the NWFSC shelf-slope surveys select both young and old fish in contrast to the other data sources where typically only larger fish were observed.

Discard lengths from the Pikitch data (1986) and the WCGOP were fit well by the model and show no obvious pattern in the residuals (Figure 42). The residuals to the fishery lengths clearly showed the growth differential between males and females where the majority of residuals at larger sizes were from female fish (Figure 43). The fishery showed large positive residuals for smaller fish for 2013-2016 which are attributed to the strong 2008 year class moving through the fishery. The At-sea hake fishery did not show an obvious pattern in residuals but clearly showed the selectivity of the fishery for larger fish (Figure 44). The residuals for each of the surveys are shown in Figures 45, 46, 47, 48, and 49. The Pearson residuals from the NWFSC shelf-slope survey clearly showed the strong year classes moving through the population.

The model was weighted according to the Francis weights which adjust the weight given to a data set based on the fit to the mean lengths by year. The mean lengths and the estimated model fits are shown in Figures 50, 51, 52, 53, 54, 55, and 56. The mean lengths from the fishery were consistent across the sampled period (Figure 68), showing only a decline in the mean length in 2013-2015 likely due to the large 2008 cohort. The At-sea hake fishery showed and increase in the mean length of fish observed to 2009 and then fluctuated at larger mean lengths (Figure 69). The Triennial survey had a decreasing and then increasing trend in the mean lengths over the sample period (Figure 53). The trend in the mean lengths observed by the AFSC slope survey was generally flat excluding the samples from 1997 which were smaller fish (Figure 54). The NWFSC slope length data from 2001 and 2002 were highly variable with differing mean lengths between the years which were not fit well by the model (Figure 55). The mean length for the NWFSC shelf-slope survey declined in 2012 and 2016 due to a large observation of young small fish by the survey (Figure 56).

Age data were fitted to as marginal age compositions for the main fishery fleet, the At-sea hake fleet, the Pacific ocean perch survey, the Triennial survey, and the NWFSC slope survey. The NWFSC shelf-slope ages were treated as conditional age-at-length data in order to facilitate the estimation of growth within the model. The aggregated fits to the marginal age data are shown in Figure 57. The aggregated age data was fit well for the fishery fleet which had the largest sample of ages. The At-sea hake fleet and the surveys had significantly lower sample sizes which resulted in spikey patterns in the aggregated data. However, the model generally captured the trend of the data. Detailed fits to the age data by year and fleet are provided in Appendix 11.

The Pearson residuals for the main fishery fleet are show in Figure 58. There are diagonal patterns in the residuals across year which likely are cohorts moving through the fishery. The At-sea hake fishery only had age data for four non-consecutive years, combined with the tendency of this fleet to select older fish, prevented general conclusions regarding fits to the data over time and cohort strength over time (Figure 59). The Pacific ocean perch survey only had one year of age data (the 1979 were all surface reads) but both sexes had a larger observed number of older fish relative to the model estimate (Figure 60). The Triennial age data which ranged from 1989-2004 did not show a clear pattern in residuals (Figure 61). However, the final year of the survey, 2004, did have an increase in positive residuals for female fish compared to earlier years. The Pearson residuals for the two years of age data from NWFSC slope survey are shown in Figure 62. The residual pattern differs between the years and by sex with positive residuals of male fish across ages in the 2001 data.

The observed and expected age-at-length are shown in Figures 63, 64, 65, 66, and 66 for the NWFSC shelf-slope survey observations. The fits generally match the observations. Some outliers are apparent with large residuals. The 2016 data varies from previous years where larger fish across all ages have higher observations compared to the model expectation.

The age data were also weighted according the Francis weighting which adjust the weight given to a data set based on the fit to the mean lengths by year. The mean age and the estimated model fits are shown in Figures 68, 69, 70, 71, and 72. The mean ages from the fishery appear to have declined in recent years which could be due to incoming cohorts (Figure 68). The At-sea hake fishery mean age are similar for 2006 and 2007 but both 2003 and 2014 have lower average age in the samples (Figure 69). The mean age for the Triennial survey varied across the sampling period but the distribution of sampled ages were highly variable across the years (Figure 70). The NWFSC slope had a decline in the mean age between the two data years (Figure 71). The mean age for the NWFSC shelf-slope survey generally showed a declining trend over the time-series excluding 2012 and 2016 which sampled older fish relative to the surrounding years (Figure 72).

3.4.3 Population trajectory

The predicted spawning output (in millions of eggs) is given in Table 26 and plotted in Figure 73. The predicted spawning output from the base model generally showed a slight decline over the time-series until when the foreign fleet began. A short, but sharp decline occurred during the period of the foreign fishery in the late 1960s. The stock continued to decline minimally until 2000 when a combination of strong recruitment and low catches resulted in an increase at the end of the time-series. The recent increase is even faster for total biomass (Figure 74) because not all fish from the 2008 recruitment are mature (Figure 26). The 2017 spawning biomass relative to unfished equilibrium spawning biomass is above the target of 40% of unfished spawning biomass (76.1%), with a low of 34.5% in 1994 (Figure 75). Approximate confidence intervals based on the asymptotic variance estimates show that the uncertainty in the estimated spawning biomass is high, especially in the early years. The standard deviation of the log of the spawning biomass in 2017 is 0.28.

Recruitment deviations were estimated for the entire time series that was modeled (Figure 37 and discussed in Section 3.4.1) and provide a more realistic portrayal of uncertainty. Recruitment predictions from the mid-1970s and early 1980s were mostly below average, with the 1999, 2000, 2008, and 2013 cohorts being the strongest over the modeled period. Many other stock assessments of rockfish along the west coast of the US have estimated a large recruitment event in 1999 (e.g., greenstriped rockfish (Hicks et al. 2009) chilipepper rockfish (Field 2007), darkblotched rockfish (Gertseva et al. 2015)). The 2008 year classes was estimated as the strongest year class. This year has been estimated to have very strong year classes for other West Coast stocks (e.g darkblotched rockfish (Gertseva et al. 2015), widow rockfish (Hicks and Wetzel 2015)). It may be worthwhile to investigate the periods of strong and weak year classes further to see if it is an artifact of the data, a consistent autocorrelation, or a result of the environment.

The stock-recruit curve resulting from a fixed value of steepness is shown in Figure 76 with estimated recruitments also shown. The stock is predicted to have never fallen to low enough levels that the steepness is obvious. However, the lowest levels of predicted spawning biomass showed some of the smallest recruitments and very few above average recruitments. Steepness was not estimated in this model, but sensitivities to alternative values of steepness are discussed below.

3.4.4 Uncertainty and Sensitivity Analyses

A number of sensitivity analyses were conducted, including:

1. Data weighting according to the harmonic mean.
2. Fixed steepness at the prior value of 0.72.

3. Estimate natural mortality for female and male Pacific ocean perch.
4. Maturity relationship used in the previous assessment.
5. Fecundity relationship used in the previous assessment.
6. Split the Triennial survey into two time-series, early (1980-1992) and late (1995-2004).
7. Remove the historical commercial CPUE index.
8. Inclusion of available Canadian fishery and survey data (does not constitute all data used in Canadian assessments).
9. Inclusion of historical Washington research lengths.
10. Inclusion of Oregon special projects length and age data which are sampled at the dockside or processing facilities.

Likelihood values and estimates of key parameters from each sensitivity are available in Tables 27 and 28. Plots of the estimated time-series of spawning output and relative biomass are shown in Figures 77, 78, 79, and 80.

The sensitivities which explored steepness or natural mortality had the largest change in estimated stock status relative to the base model. Fixing steepness at the prior value resulted in the stock being near unfished spawning biomass output. When natural mortality was estimated the estimated values were higher relative to the median of the prior used in base model, resulting in the relative biomass to be $> 93\%$.

Including additional data from either Canada, Washington research lengths, and or Oregon special projects data resulted in estimated lower stock status relative to the base model. However, the status was still well above the management target.

Weighting the data according to the harmonic means resulted in the largest decrease in the estimated stock status relative to the base model with the stock being estimated at 68% of unfished biomass.

The sensitivities that explored the removal of the CPUE index, the 2011 maturity, or fecundity relationship had little impact relative to the base model results.

3.4.5 Retrospective Analysis

A 5-year retrospective analysis was conducted by running the model using data only through 2011, 2012, 2013, 2014, and 2015, progressively (Figure 81 and 82). The initial scale of the spawning population was basically unchanged for all of these retrospectives. The estimation of the 2008 recruitment deviation decreased as more data was removed. Overall, no alarming trends were present in the retrospective analysis.

3.4.6 Likelihood Profiles

Likelihood profiles were conducted for R_0, steepness, and over natural mortality values separately. These likelihood profiles were conducted by fixing the parameter at specific values and estimated the remaining parameters based on the fixed parameter value.

For steepness, the negative log-likelihood was essentially flat between values of 0.30 - 0.80 (Figure 83). Likelihood components by data source show that the fishery length and age data supports a low steepness value, but the NWFSC shelf-slope age data supports a higher value for steepness. The Triennial survey index indicates a low value of steepness while the other surveys do not provide information concerning steepness. The relative biomass for Pacific ocean perch has a wide range across different assumed values of steepness (Figure 84).

The negative log-likelihood was minimized at a natural mortality value of 0.06, but the 95% confidence interval extends over the majority of natural mortality values. The age and length data likelihood contribution was minimized at natural morality values ranging from 0.055-0.06 (Figure 85). The relative biomass for Pacific ocean perch widely varied across alternative values of natural mortality (Figure 86).

In regards to values of R_0, the negative log-likelihood was minimized at approximately $\log(R_0)$ of 9.30 (Figure 87). The fishery and survey composition data was in opposition regarding values of R_0 where the fishery length and age data indicated lower values of R_0 while the survey ages from the Pacific ocean perch and the NWFSC shelf-slope surveys indicated a higher value.

3.4.7 Reference Points

Reference points were calculated using the estimated selectivities and catch distribution among fleets in the most recent year of the model (2016). Sustainable total yields (landings plus discards) were 1764.8 mt when using an $SPR_{50\%}$ reference harvest rate and with a 95% confidence interval of 1264.8 - 2264.8 mt based on estimates of uncertainty. The spawning output equivalent to 40% of the unfished spawning output ($SB_{40\%}$) was 2653.2 millions of eggs. The recent catches (landings plus discards) have been below the point estimate of potential long-term yields calculated using an $SPR_{50\%}$ reference point and the population has been increasing over the last decade.

The predicted spawning biomass from the base model generally showed a sharp decline during the 1960s, steep increase above unfished equilibrium levels, followed by less of a decline until 2001 (Figure 73). Since 2001, the spawning biomass has been increasing due to small catches, and recently, above average recruitment. The 2017 spawning biomass relative to unfished equilibrium spawning biomass is above the target of 40% of unfished spawning biomass (Figure 75). The fishing intensity, $(1 - SPR)/(1 - SPR_{50\%})$, exceeded the current estimates of the harvest rate limit ($SPR_{50\%}$) throughout the 1960s as seen in Figure 88.

Recent exploitation rates on Pacific ocean perch were predicted to be much less than target levels. In recent years, the stock has experienced exploitation rates that have been below the target level while the biomass level has remained above the target level.

Table 25 shows the full suite of estimated reference points for the base model and Figure 89 shows the equilibrium curve based on a steepness value fixed at 0.50.

4 Harvest Projections and Decision Tables

A twelve year projection of the base model with catches equal to the estimated ACL for years 2019-2028 and a catch allocation equal to the percentages for each fleet over the period of 2014-2016 predicts an increase in the spawning output due to large 2008 cohort, with a slight downturn beginning in 2023 (Table 29).

Add additional projection post STAR based upon the decision table.

Table 30

5 Regional Management Considerations

The distribution of Pacific ocean perch occur primarily in the US west coast waters of Washington, Oregon, and northern California and hes is currently managed to a species level with harvest limits set for the stock north of the $40°10'$ latitude. The population within this area is treated as a single stock due to the lack of biological and genetic data indicating the presence of multiple stocks. Analysis conducted within this assessment did not find support for regional management within the area that Pacific ocean perch occur.

6 Research Needs

There are many areas of research that could be improved to benefit the understanding and assessment of Pacific ocean perch. Below, are issues that are considered of the importance.

1. **Natural mortality**: Uncertainty in natural mortality translates into uncertain estimates of status and sustainable fishing levels for Pacific ocean perch. The collection of additional age data, re-reading of older age samples, reading old age samples that are unread, and improved understanding of the life-history of Pacific ocean perch may reduce that uncertainty.

2. **Steepness**: The amount of stock resilience, steepness, dictates the rate at which a stock can rebuild from low stock sizes. Improved understanting regarding the steepness of US west coast Pacific ocean perch will reduce our uncertainty regarding current stock status.

3. **Basin-wide understanding of stock structure, biology, connectivity, and distribution:** This is a stock assessment for Pacific ocean perch off of the west coast of the US and does not consider data from British Columbia or Alaska. Further investigating and comparing the data and predictions from British Columbia and Alaska to determine if there are similarities with the US west Ccast observations would help to define the connectivity between Pacific ocean perch north and south of the U.S.-Canada border.

7 Acknowledgments

Many people were instrumental in the successful completion of this assessment and their contribution is greatly appreciated. Jason Cope (NWFSC), Ian Taylor (NWFSC), and Owen Hamel (NWFSC), contributed greatly with discussions about data, modeling, and SS. Allan Hicks (IPHC) provided guidance on model approaches and data exploration. We are grateful to Theresa Tsou (WDFW) and Phillip Wyland (WDFW) who provided research data and the first historical reconstruction of catch for Washington state. Ali Whitman (ODFW), Patrick Mirrick (ODFW), and Ted Calavan (ODFW) provided Oregon composition data, historical catches, corrected PacFIN catches, and quickly uploaded age data that were critical to this assessment. We appreciate Vanessa Tuttle's patience and responsiveness to providing data. Don Pearson (NOAA) provided historical catch information and compiled the extensive management changes for Pacific ocean perch which were critical in understanding and modeling fishery behavior. John Wallace provided multiple last minute PacFIN extractions and analyzed historical discard rates for use in the assessment.

We are very grateful to Patrick McDonald and the team of agers at CAP for their hard work reading numerous otoliths and availability to answer questions when needed. Beth Horness was always eager to help, quick to supply survey extractions, and answered numerous questions we had. Jason Jannot and Kayleigh Sommers assisted with data from the WCGOP and entertained our many questions. We would like to acknowledge our survey team and their dedication to improving the assessments we do. The assessment was greatly improved through the many discussions within the Population Ecology team in the FRAM division at the NWFSC.

Table 2: West Coast history of regulations.

Date	Area	Regulation
11/10/1983	Columbia	Closed Columbia area to Pacific ocean perch fishing until the end of the year, as 950 mt OY for this species has been reached;
11/10/1983	Vancouver	retained 5,000-pound trip limit or 10% of total trip weight on landings of Pacific ocean perch in the Vancouver area.
1/1/1984	ALL	Continued 5,000-pound trip limit or 10% of total trip weight on Pacific ocean perch as specified in FMP. Fishery to close when area OYs are reached (see action effective November 10, 1983 above).
8/1/1984	Vancouver Columbia	Reduced trip limit for Pacific ocean perch in the Vancouver and Columbia areas to 20% by weight of all fish on board, not to exceed 5,000 pounds per vessel per trip.
8/16/1984	Columbia	Commercial fishing for Pacific ocean perch in the Columbia area closed for remainder of the year.
1/10/1985	Vancouver Columbia	Established Vancouver and Columbia areas Pacific ocean perch trip limit of 20% by weight of all fish on board (no 5,000-pound limit as specified in last half of 1984).
4/28/1985	Vancouver Columbia	Reduced the Vancouver and Columbia areas Pacific ocean perch trip limit to 5,000 pounds or 20% by weight of all fish on board, whichever is less.
4/28/1985	ALL	Landings of Pacific ocean perch less than 1,000 pounds will be unrestricted. The fishery for this species will close when the OY in each area is reached.
6/10/1985	ALL	Landings of Pacific ocean perch up to 1,000 pounds per trip will be unrestricted regardless of the percentage of these fish on board.
1/1/1986	Cape Blanco North	Established the Pacific ocean perch trip limit north of Cape Blanco (4250) at 20% (by weight) of all fish on board or 10,000 pounds whichever is less;
1/1/1986	ALL	landings of Pacific ocean perch unrestricted if less than 1,000 pounds regardless of percentage on board; Vancouver area OY = 600 mt; Columbia area OY =950 mt.
12/1/1986	Vancouver	OY quota for Pacific ocean perch reached in the Vancouver area; fishery closed until January 1, 1987.
1/1/1987	ALL	Established coastwide Pacific ocean perch limit at 20% of all legal fish on board or 5,000 pounds whichever is less (in round weight); landings of Pacific ocean perch unrestricted if less than 1,000 pounds regardless of percentage on board; Vancouver area OY =500 mt; Columbia area OY = 800 mt.
1/1/1988	ALL	Established the coastwide Pacific ocean perch trip limit at 20% (by weight) of all fish on board or 5,000 pounds, whichever is less; landings of Pacific ocean perch unrestricted if less than 1,000 pounds regardless of percentage on board;
1/1/1989	ALL	Established the coastwide Pacific ocean perch trip limit at 20% (by weight) of all fish on board or 5,000 pounds whichever is less;
1/1/1989	ALL	landings of Pacific ocean perch unrestricted if less than 1,000 pounds regardless of percentage on board (Vancouver area OY =500 mt; Columbia area OY =800 mt).
7/26/1989	ALL	Reduced the coastwide trip limit for Pacific ocean perch to 2,000 pounds or 20% of all fish on board, whichever is less, with no trip frequency restriction.
12/13/1989	Columbia	Closed the Pacific ocean perch fishery in the Columbia area because 1,040 mt OY reached.
1/1/1990	ALL	Established the coastwide Pacific ocean perch trip limit at 20% (by weight) of all fish on board or 3,000 pounds whichever is less; landings of Pacific ocean perch be unrestricted if less than 1,000 pounds regardless of percentage on board. (Vancouver area OY = 500 mt; Columbia area OY = 1,040 mt).
1/1/1991	ALL	Established the coastwide Pacific ocean perch trip limit at 20% (by weight) of all groundfish on board or 3,000 pounds whichever is less; landings of Pacific ocean perch be unrestricted if less than 1,000 pounds regardless of percentage on board (harvest guideline for combined Vancouver and Columbia areas = 1,000 mt).
1/1/1992	ALL	For Pacific ocean perch, established the coastwide trip limit at 20% (by weight) of all groundfish on board or 3,000 pounds whichever is less; landings of Pacific ocean perch be unrestricted if less than 1,000 pounds regardless of percentage on board (harvest guideline for combined Vancouver and Columbia areas = 1,550 mt).

Date	Area	Regulation
1/1/1993	Cape Mendocino Coos Bay	For Pacific ocean perch, continued the coastwide trip limit at 20% (by weight) of all groundfish on board or 3,000 pounds whichever is less; landings of Pacific ocean perch unrestricted if less than 1,000 pounds regardless of percentage on board (harvest guideline for combined Vancouver and Columbia areas = 1,550 mt).
1/1/1994	ALL	Pacific Ocean Perch trip limit of 3,000 pounds or 20% of all fish on board, whichever is less, in landings of Pacific ocean perch above 1,000 pounds.
1/1/1995	ALL	For Pacific Ocean Perch, established a cumulative trip limit of 6,000 pounds per month
1/1/1996	ALL	Pacific Ocean Perch cumulative trip limit of 10,000 pounds per two-month period.
7/1/1996	4030 North	Reduced the cumulative 2-month limit for Pacific ocean perch to 8,000 pounds, and established the cumulative 2-month limit for Dover sole north of Cape Mendocino at 38,000 pounds
1/1/1997	ALL	Pacific Ocean Perch limited entry fishery cumulative trip limit of 8,000 pounds per two-month period
1/1/1998	ALL	Pacific Ocean Perch: limited entry fishery Cumulative trip limit of 8,000 pounds per two-month period.
7/1/1998	ALL	Open Access Rockfish: removed overall rockfish monthly limit and replaced it with limits for component rockfish species: for Sebastes complex, monthly cumulative limit is 33,000 pounds, for widow rockfish, monthly cumulative trip limit is 3,000 pounds, for Pacific Ocean Perch, monthly cumulative trip limit is 4,000 pounds.
1/1/1999	ALL	for the limited entry fishery A new three phase cumulative limit period system is introduced for 1999. Phase 1 is a single cumulative limit period that is 3months long, from January 1 - March 31. Phase 2 has 3 separate 2 month cumulative limit periods of April 1 - May 31, June 1 - July 31, and August 1 - September 30. Phase 3 has 3 separate 1 month cumulative limit periods of October 1-31, November 1-30, and December 1-31. For all species except Pacific ocean perch and Bocaccio, there will be no monthly limit within the cumulative landings limit periods. An option to apply cumulative trip limits lagged by 2 weeks (from the 16th to the 15th) was made available to limited entry trawl vessels when their permits were renewed for 1999. Vessels that are authorized to operate in this ”B” platoon may take and retain, but may not land, groundfish during January 1-15, 1999.
1/1/1999	ALL	for the limited entry fishery Pacific Ocean Perch: cumulative limit, Phase 1: 4,000 pounds per month; Phase 2: 4,000 pounds per month; Phase 3: 4,000pounds per month.
1/1/1999	ALL	for open access gear: Pacific Ocean Perch: coastwide, 100 pounds per month.
1/1/2000	ALL	Limited entry trawl, Pacific Ocean Perch, 500 lbs per month
1/1/2000	ALL	Pacific Ocean Perch, Open Access gear except exempted trawl, 100 lbs per month
1/1/2000	ALL	Pacific Ocean Perch, limited entry fixed gear, 500 lbs per month
5/1/2000	ALL	Limited entry trawl, Pacific Ocean Perch, 2500 lbs per 2 months
5/1/2000	ALL	Pacific Ocean Perch, limited entry fixed gear, 2500 lbs per month
11/1/2000	ALL	Limited entry trawl, Pacific Ocean Perch, 500 lbs per month
11/1/2000	ALL	Pacific Ocean Perch, limited entry fixed gear, 500 lbs per month
1/1/2001	3600 North	Pacific Ocean Perch, open access, 100 lbs per month
1/1/2001	4010 North	Pacific Ocean Perch, limited entry trawl, 1500 lbs per mont
1/1/2001	ALL	Pacific Ocean Perch, limited entry fixed gear, 1500 lbs per month
5/1/2001	4010 North	Pacific Ocean Perch, limited entry trawl, 2500 lbs per month
5/1/2001	ALL	Pacific Ocean Perch, limited entry fixed gear, 2500 lbs per month
10/1/2001	4010 North	Pacific Ocean Perch, limited entry trawl, 1500 lbs per month
11/1/2001	ALL	Pacific Ocean Perch, limited entry fixed gear, 1500 lbs per month
1/1/2002	4010 North	Pacific Ocean Perch, open access, 100 lbs per month
1/1/2002	4010 North	Pacific Ocean Perch, limited entry fixed gear, 2000 lbs per month
1/1/2002	4010 North	Pacific Ocean Perch, limited entry trawl, 2000 lbs per month
4/1/2002	4010 North	Pacific Ocean Perch, limited entry fixed gear, 4000 lbs per month
5/1/2002	4010 North	Pacific Ocean Perch, limited entry trawl, 4000 lbs per month
11/1/2002	4010 North	Pacific Ocean Perch, limited entry fixed gear, 2000 lbs per month
11/1/2002	4010 North	Pacific Ocean Perch, limited entry trawl, 2000 lbs per month
1/1/2003	3800 South	minor slope rockfish south including pacific ocean perch, open access gear, 10000 lbs per 2 months

Date	Area	Regulation
1/1/2003	3800 South	Minor slope rockfish south including Pacific ocean perch, limited entry fixed gear, 30000 lbs per 2 months
1/1/2003	3800 South	Minor slope rockfish south including Pacific ocean perch , limited entry trawl, 30000 lbs per 2 months
1/1/2003	3800 4010	minor slope rockfish south including pacific ocean perch, open access gear, per trip no more than 25% (by weight) of sablefish landed
1/1/2003	3800 4010	Minor slope rockfish south including Pacific ocean perch, limited entry fixed gear, 1800 lbs per 2 months
1/1/2003	3800 4010	Minor slope rockfish south including Pacific ocean perch , limited entry trawl, 1800 lbs per 2 months
1/1/2003	4010 North	pacific ocean perch, open access gears, 100 lbs per month
1/1/2003	4010 North	pacific ocean perch, limited entry fixed gear, 1800 lbs per 2 months
1/1/2003	4010 North	Pacific Ocean Perch, Limited entry trawl gear, 3000 lbs per 2 months
3/1/2003	3800 4010	Minor slope rockfish south including Pacific ocean perch, limited entry fixed gear, no more than 25% of the weight of sablefish landed per trip
11/1/2003	3800 4010	Minor slope rockfish south including Pacific ocean perch, limited entry fixed gear, 1800 lbs per 2 months
1/1/2004	3800 South	Minor slope rockfish south including Pacific ocean perch, open access gear, 10000 lbs per 2 months
1/1/2004	3800 South	minor slope rockfish south inclding pacific ocean perch, limited entry fixed gear, 40000 lbs per 2 months
1/1/2004	3800 South	minor slope rockfish south including pacific ocean perch, limited entry trawl, 40000 lbs per 2 months
1/1/2004	3800 4010	Minor slope rockfish south including Pacific ocean perch, open access gear, per trip no more than 25% of the weight of sablefish landed
1/1/2004	3800 4010	minor slope rockfish south including pacific ocean perch, limited entry fixed gear, 7000 lbs per 2 months
1/1/2004	3800 4010	minor slope rockfish south including pacific ocean perch, limited entry trawl, 7000 lbs per 2 months
1/1/2004	4010 North	pacific ocean perch, open access gear, 100 lbs per month
1/1/2004	4010 North	pacific ocean perch, limited entry fixed gear, 1800 lbs per 2 months
1/1/2004	4010 North	pacific ocean perch, limited entry trawl, 3000 lbs per 2 months
5/1/2004	3800 South	minor slope rockfish south inclding pacific ocean perch, limited entry fixed gear, 50000 lbs per 2 months
5/1/2004	3800 South	minor slope rockfish south including pacific ocean perch, limited entry trawl, 50000 lbs per 2 months
5/1/2004	3800 4010	minor slope rockfish south including pacific ocean perch, limited entry fixed gear, 50000 lbs per 2 months
5/1/2004	3800 4010	minor slope rockfish south including pacific ocean perch, limited entry trawl, 50000 lbs per 2 months
11/1/2004	3800 South	minor slope rockfish south inclding pacific ocean perch, limited entry fixed gear, 50000 lbs per 2 months
11/1/2004	3800 South	minor slope rockfish south including pacific ocean perch, limited entry trawl, 50000 lbs per 2 months
11/1/2004	3800 4010	minor slope rockfish south including pacific ocean perch, limited entry fixed gear, 10000 lbs per 2 months
11/1/2004	3800 4010	minor slope rockfish south including pacific ocean perch, limited entry trawl, 10000 lbs per 2 months
1/1/2005	3800 South	minor slope rockfish south including darkblotched and pacific ocean perch, open access gear, 10000 lbs per 2 months
1/1/2005	3800 South	minor slope rockfish south including darkblotched rockfish and pacific ocean perch, limited entry trawl, closed
1/1/2005	3800 4010	minor slope rockfish south including darkblotched and pacific ocean perch, open access gear, per trip no more than 25% of weight of sablefish onboard
1/1/2005	3800 4010	minor slope rockfish south including darkblotched rockfish and pacific ocean perch, limited entry trawl, 4000 lbs per 2 months
1/1/2005	4010 North	pacific ocean perch, open access gears, 100 lbs per month
1/1/2005	4010 North	pacific ocean perch, limited entry trawl gear, 3000 lbs per 2 months
1/1/2005	4010 North	pacific ocean perch, limited entry fixed gear, 1800 lbs per 2 months
1/1/2005	4010 South	minor slope rockfish south including darkblotched and pacific ocean perch, limited entry fixed gear, 40000 lbs per 2 months
5/1/2005	3800 4010	minor slope rockfish south including darkblotched rockfish and pacific ocean perch, limited entry trawl, 8000 lbs per 2 months

Date	Area	Regulation
1/1/2008	3800 4010	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, limited entry trawl, 15000 lbs per 2 months
1/1/2008	4010 North	pacific ocean perch, limited entry trawl, 1500 lbs per 2 months
1/1/2009	4010 North	pacific ocean perch, limited entry fixed gear, 1800 lbs per 2 months
1/1/2009	4010 South	minor slope rockfish south including pacific ocean perch and darkblotched, limited entry fixed gear, 40000 lbs per 2 months
1/1/2009	3800 South	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, open access gear, 10000 lbs per 2 months
1/1/2009	3800 4010	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, open access gear, per trip no more than 25% (by weight) of sablefish landed
1/1/2009	4010 North	pacific ocean perch, open access gears, 100 lbs per month
1/1/2009	3800 South	minor slope rockfish southincluding pacific ocean perch and darkblotched rockfish, limited entry trawl, 55000 lbs per 2 months
1/1/2009	3800 4010	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, limited entry trawl, 15000 lbs per 2 months
1/1/2009	4010 North	pacific ocean perch, limited entry trawl, 1500 lbs per 2 months
7/1/2009	3800 4010	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, limited entry trawl, 10000 lbs per 2 months
11/1/2009	3800 4010	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, limited entry trawl, 15000 lbs per 2 months
1/1/2010	4010 North	pacific ocean perch, limited entry fixed gear, 1800 lbs per 2 months
1/1/2010	4010 South	minor slope rockfish south including pacific ocean perch and darkblotched,limited entry fixed gear, 40000 lbs per 2 months
1/1/2010	3800 South	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, open access gear, 10000 lbs per 2 months
1/1/2010	3800 4010	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, open access gear, per trip no more than 25% (by weight) of sablefish landed
1/1/2010	4010 North	pacific ocean perch, open access gears, 100 lbs per month
1/1/2010	3800 South	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, limited entry trawl, 55000 lbs per 2 months
1/1/2010	3800 4010	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, limited entry trawl, 15000 lbs per 2 months
1/1/2010	4010 North	pacific ocean perch, limited entry trawl, 1500 lbs per 2 months
1/1/2011	4010 North	pacific ocean perch, limited entry fixed gear, 1800 lbs per 2 months
1/1/2011	4010 South	minor slope rockfish south including pacific ocean perch and darkblotched, limited entry fixed gear, 40000 lbs per 2 months
1/1/2011	3800 South	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, open access gear, 10000 lbs per 2 months
1/1/2011	3800 4010	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, open access gear, per trip no more than 25% (by weight) of sablefish landed
1/1/2011	4010 North	pacific ocean perch, open access gears, 100 lbs per month
1/1/2011	ALL	Pacific Ocean Perch managed in part by IFQ
1/1/2012	4010 North	pacific ocean perch, limited entry fixed gear, 1800 lbs per 2 months
1/1/2012	4010 South	minor slope rockfish southincluding pacific ocean perch and darkblotched, limited entry fixed gear, 40000 lbs per 2 months
1/1/2012	3800 South	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, open access gear, 10000 lbs per 2 months
1/1/2012	3800 4010	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, open access gear, per trip no more than 25% (by weight) of sablefish landed
1/1/2012	4010 North	pacific ocean perch, open access gears, 100 lbs per month
1/1/2013	4010 North	pacific ocean perch, open access gears, 100 lbs per month
1/1/2013	4010 North	pacific ocean perch, limited entry fixed gear, 1800 lbs per 2 months
1/1/2013	4010 South	minor slope rockfish south including pacific ocean perch and darkblotched, limited entry fixed gear, 40000 lbs per 2 months no more than 1375 lbs may be blackgill
1/1/2013	4010 South	minor slope rockfish south including pacific ocean perch and darkblotched rockfish, open access gear, 10000 lbs per 2 months no more than 475 lbs of which may be blackgill rockfish
1/1/2014	4010 North	non-trawl, limited entry, pacific ocean perch, 1800 lbs per 2 months
1/1/2014	4010 South	non-trawl, limited entry, minor slope rockfish and darkblotched rockfish and pacific ocean perch, 40000 lbs per 2 months of which no more than 1375 lbs may be blackgill rockfish

Date	Area	Regulation
1/1/2014	4010 North	non-trawl, open access, pacific ocean perch, 100 lbs per month
1/1/2014	4010 South	non-trawl, open access, minor slope rockfish including darkblotched rockfishand pacific ocean perch, 10000 lbs per 2 months of which no more than 475 lbs may be blackgill rockfish
1/1/2015	4010 North	non-trawl, limited entry, pacific ocean perch, 1800 lbs per 2 months
1/1/2015	4010 South	non-trawl, limited entry, minor slope rockfish and darkblotched rockfish and pacific ocean perch, 40000 lbs per 2 months of which no more than 1375 lbs may be blackgill rockfish
1/1/2015	4010 North	non-trawl, open access, pacific ocean perch, 100 lbs per month
1/1/2015	4010 South	non-trawl, open access, minor slope rockfish including darkblotched rockfishand pacific ocean perch, 10000 lbs per 2 months of which no more than 475 lbs may be blackgill rockfish
7/1/2015	4010 South	non-trawl, limited entry, minor slope rockfish and darkblotched rockfish and pacific ocean perch, 40000 lbs per 2 months of which no more than 1600 lbs may be blackgill rockfish
7/1/2015	4010 South	non-trawl, open access, minor slope rockfish including darkblotched rockfishand pacific ocean perch, 10000 lbs per 2 months of which no more than 550 lbs may be blackgill rockfish
1/1/2016	4010 North	non-trawl, limited entry, pacific ocean perch, 1800 lbs per 2 months
1/1/2016	4010 North	non-trawl, open access, pacific ocean perch, 100 lbs per month
1/1/2016	4010 South	non-trawl, open access, minor slope rockfish including darkblotched rockfishand pacific ocean perch, 10000 lbs per 2 months of which no more than 475 lbs may be blackgill rockfish
7/1/2016	4010 South	non-trawl, open access, minor slope rockfish including darkblotched rockfishand pacific ocean perch, 10000 lbs per 2 months of which no more than 550 lbs may be blackgill rockfish

Table 3: Recent trend in estimated total catch relative to management guidelines.

Year	OFL (mt; ABC prior to 2011)	ABC (mt)	ACL (mt; OY prior to 2011)	Total landings (mt)	Estimated total catch (mt)
2007	900		150	133	157
2008	911		150	92	133
2009	1,160		189	94	190
2010	1,173		200	97	181
2011	1,026	981	180	60	61

Table 21: Specifications of the base model for Pacific ocean perch.

Model Specification	Base Model
Starting year	1918
Population characteristics	
Maximum age	60
Gender	2
Population lengths	5-50 cm by 1 cm bins
Summary biomass (mt)	Age 3+
Data characteristics	
Data lengths	11-47 cm by 1 cm bins
Data ages	1-40
Minimun age for growth calculations	3
Maximum age for growth calculations	20
First mature age	0
Starting year of estimated recruitment	1940
Fishery characteristics	
Fishery timing	mid-year
Fishing mortality method	discrete
Maximum F	0.9
Catchability	Analytical estimate
Fishery selectivity	Double Normal
At-Sea Hake selectivity	Double Normal
POP survey selectivity	Logistic
Triennial survey	Double Normal
AFSC slope survey	Double Normal
NWFSC slope survey	Double Normal
NWFSC shelf/slope survey	Double Normal
Fishery time blocks	
Fishery selectivity	none
Fishery retention	1918-1991, 1992-2001, 2002-2007, 2008, 2009-2010, 2011-2016

Table 22: Results from 100 jitters from the base model.

Status	Base.Model
Returned to base case	33
Found local minimum	45
Found better solution	0
Error in likelihood	22
Total	100

Table 24: Likelihood components from the base model

Likelihood Component	Value
Total	1726.16
Survey	0
Discard	-25.51
Length-frequency data	-34.22
Age-frequency data	135.74
Recruitment	1636.59
Forecast Recruitment	12.54
Parameter Priors	0

Table 25: Summary of reference points and management quantities for the base case.

Quantity	Estimate	~95% Confidence Interval
Unfished spawning output (million eggs)	6633.1	4736.7 - 8529.5
Unfished age 3+ biomass (mt)	139810	100052.5 - 179567.5
Unfished recruitment (R0, thousands)	11665.7	8801.4 - 15462.1
Spawning output(2017 million eggs)	5047.2	2259.2 - 7835.1
Depletion (2017)	0.761	0.538 - 0.984
Reference points based on $\mathbf{SB_{40\%}}$		
Proxy spawning output ($B_{40\%}$)	2653.2	1894.7 - 3411.8
SPR resulting in $B_{40\%}$ ($SPR_{B40\%}$)	0.55	0.55 - 0.55
Exploitation rate resulting in $B_{40\%}$	0.028	0.028 - 0.029
Yield with $SPR_{B40\%}$ at $B_{40\%}$ (mt)	1748.2	1252.4 - 2244
Reference points based on SPR proxy for MSY		
Spawning output	2211	1578.9 - 2843.2
SPR_{proxy}	0.5	
Exploitation rate corresponding to SPR_{proxy}	0.034	0.033 - 0.034
Yield with SPR_{proxy} at SB_{SPR} (mt)	1764.8	1264.8 - 2264.8
Reference points based on estimated MSY values		
Spawning output at MSY (SB_{MSY})	2315.7	1649.6 - 2981.8
SPR_{MSY}	0.512	0.51 - 0.514
Exploitation rate at MSY	0.032	0.032 - 0.033
MSY (mt)	1766.7	1266.1 - 2267.4

Table 26: Time-series of population estimates from the base model.

Year	Total biomass (mt)	Spawning output (million eggs)	Summary biomass 3+	Relative biomass	Age-0 re-cruits	Estimated total catch (mt)	1-SPR	Exp. rate
1918	140160	6644	139432	1.00	11773	0	0	0

Table 30: Summary of 10-year projections beginning in 2019 for alternate states of nature based on an axis of uncertainty for the base model. Columns range over low, mid, and high states of nature, and rows range over different assumptions of catch levels. An entry of "–" indicates that the stock is driven to very low abundance under the particular scenario.

			States of nature
